Deadpooling:
Strategic Adverse Selection in the Medigap Market

UC Berkeley

Margaret Kallus* and Elaine Shen†

October 9, 2026

Abstract

Adverse selection is a well-known problem in health insurance markets. To prevent consumers from delaying coverage until they need high levels of care and prevent firms from extracting rents on people with high demand for insurance, governments may implement a series of regulations to constrain both buyers and sellers. This paper examines a case of this in the Medicare Supplement market. Linking two decades of Medicare Supplement filings to annual parent–subsidiary ownership records, we document *deadpooling*, a novel financial practice where insurers use corporate structure to circumvent regulation and extract rents from high-risk consumers. 17.6% of Medigap life-years through 2020 are spent in plans that deadpool, and each year's closures transfer an additional $114.9 million from seniors to insurer profits over the following five years. This extraction is a choice rather than the arithmetic of an aging pool. Using a natural experiment in which a federal statute effectively closed some types of plan to new enrollment, we find that deadpooling plans of the same type reprice much more aggressively than plans that slowly age in place. Harm to consumers accrues through increased payments to insurers, switching costs, and deadweight loss from beneficiaries priced out of the market who cannot get plans from other insurers, and it totals $149.5 million for each year's closures over the same five years. Each dollar of deadpooling markup collected by insurers costs seniors $1.30. We find that expanding switching rights, an intervention that would eliminate this harm in a market with perfectly rational consumers, only reduces deadpooling by 18%. We explain this finding as a consequence of consumer inattention using a demand-side simulation. We examine alternative solutions that do not rely on consumer attention, and find that these reduce harm by up to 53%, against 5% for expanded switching rights.

1 Introduction

Adverse selection is among the oldest and best-documented problems in insurance markets. Adverse selection is a market failing caused by imperfect information, and it occurs when buyers know more about their own risk than insurers are able to price. In health insurance markets, the inability to include private information in prices often derives from legislative mandates, where insurers cannot deny coverage to people with preexisting conditions or health risks during certain enrollment periods. Left alone, adverse selection can lead to a death spiral, where the healthy withdraw from the market, the pool that remains costs more to cover, and the premium that covers it drives out more of the healthy still. This spiral that can leave a competitive market with no stable equilibrium at all (Rothschild and Stiglitz 1976), and it has since been measured across a wide range of insurance settings (Einav and Finkelstein 2011, 2023). To prevent death spirals, regulators use a variety of tools to encourage low-risk enrollees to participate in the market. Common regulatory tools used to prevent advserse selection include subsidies and mandates. However, subsidies may be expensive to adminster, and mandates are historically unpopular, especially in US health insurance markets. Another way to encourage low-risk beneficiaries to purchase coverage is through long-term contracts, where enrollees select their level of coverage at a time when many people have not yet realized much of their underlying risk. Risk-averse enrollees would be motivated to purchase a higher level of coverage for a long-term plan than they would for a short-term plan, as long-term health is more uncertain. However, if there are barriers to switching between insurers, long-term contracts give firms ex-post market power over their enrollees.

We study the costs of using long-term choices to stabilize the market in the market for Medicare Supplement insurance. Medicare expenditures account for 3.8% of US GDP, much of which is subsidized by the government, so problems in this market carry budgetary and macroeconomic repercussions (Centers for Medicare and Medicaid Services 2025). Most beneficiaries age into Medicare at 65 in relatively good health, but they know that their health costs and are likely to increase as they age. Adverse selection is a particular threat to Medicare, the US's federal health insurance program for senior and disabled populations, as these groups are especially likely to require costly care. The Medicare program places bounds on how sparse or comprehensive approved coverage may be, but within these bounds individuals choose among a wide range of plans differing in benefits and cost-sharing structures. Medicare Supplement, or Medigap, policies sit at the comprehensive end of that range, covering most cost sharing in exchange for a monthly premium. Because Medigap coverage is comprehensive but expensive, one might expect a regime in which enrollees could freely opt in and out of this coverage to suffer from adverse selection. In practice, this would entail seniors waiting until they develop health conditions to pay for a Medigap and enrolling in inexpensive Medicare Advantage plans while their utilization is low. Curto (2023) finds exactly this in the small number of states with highly flexible plan switching regulation; when people can buy a Medigap at any time they like, they delay purchase, which is associated with decreased enrollment and higher annual premiums.

To prevent these effects, most states require beneficiaries to choose whether to get a Medigap when they first join Medicare. A beneficiary is guaranteed access to any Medigap plan when they first enroll at 65,

but after this initial period they must pass medical underwriting to switch insurers or policies. The people who would not pass medical underwriting are therefore locked in to their initial plan choice. This lock-in may stabilize the risk pool, but it does so at the cost of granting insurers ex-post market power over some beneficiaries. In this paper, we find that some firms use this market power to profit from locked-in enrollees. These firms use subsidiaries to segment enrollees by health status, charging a captive pool above cost while competing for healthy enrollees under a different corporate name. We call this practice *deadpooling*. This practice goes beyond the frictions studied in the switching-cost literature (Klemperer 1987, 1995; Farrell and Klemperer 2007). An ordinary switching cost is surmountable and faced by an attentive consumer, but here the barrier is prohibitive and falls on buyers whose choice sets have narrowed.

This general mechanism is not peculiar to the Medigap market. A seller who can distinguish locked-in buyers from still-mobile ones, and price to them separately, holds ex-post market power that no degree of ex-ante competition disciplines. This could apply any long-term relationship in which a seller can reset the price over time and the buyer's ability to walk away erodes, including the owner of equipment whose manufacturer uses proprietary parts (Borenstein, MacKie-Mason, and Netz 1995); an aging renter who can no longer easily pack up and move; and a car or homeowner insurance policyholder whose risk has risen would all be possible examples.

While this dynamic may appear in other settings, the Medigap market has standardized products, which makes it possible to disentangle changes in plan quality and price. Roughly 14 million Medicare beneficiaries hold one of these standardized plans today, and because any two plans carrying the same letter provide identical coverage, a premium increase after closure is purely a financial loss without any coverage gain. We construct a novel Medigap pricing and plan choice dataset from insurance filings with the NAIC (National Association of Insurance Commissioners), annual parent-subsidiary linkages from the NAIC, and highly granular pricing data from CSG Actuarial in order to estimate the prevalence and impact of deadpooling.

The scale of deadpooling is large relative to prior estimates of pricing frictions in health insurance. Using a Callaway Sant'Anna differences-in-differences design to account for the staggered nature of plan closures, we find that 17.6% of Medigap life-years through 2020 are spent in a plan that deadpools. [1] The practice transfers an estimated $298.6 million per year from seniors to insurer profits, or $5.7 billion over our sample period. This magnitude is larger than the inattention-based markups documented elsewhere in Medicare and sits alongside the health-based lock-in costs estimated in other guaranteed-renewable insurance markets. Ericson (2014) attributes a markup of about 10%, roughly $50 per enrollee per year, to consumer inertia in Medicare Part D, and Atal (2019) estimates that enrollees in Chile's guaranteed-renewable market would pay 13% more for the ability to switch. The average enrollee in a deadpooled Medigap plan pays 41.6% more per year once it closes ($1,005 on top of the $2,415 they paid before) for coverage that has not changed. Counting also the value given up by those priced out, each

1. This share counts a deadpooling plan's entire life, including the years before it closes, and so measures exposure to a plan that deadpools rather than time spent trapped. The narrower share (life-years spent inside a block that has already closed, which is the window over which the transfer below is computed) is 9.4%. The cutoff is 2020 rather than the end of the sample because the deadpooling definition requires five post-closure years in which to observe parent reentry.

year's deadpooling closures cost enrollees $223.0 million over their first five years, or $1.18 for every dollar of insurer profit.

In response to this practice, 16 states have passed additional legislation designed to increase consumers' ability to shop for new plans. Though these policies have continued to pass in many states, the efficacy of these regulations has not been studied. Using an event-study design that exploits the staggered adoption of consumer-choice legislation across states, we estimate the effects of these laws on premiums, claims, and insurer profits. Finally, we use a demand-side simulation to consider the efficacy of alternate policies in reducing lost consumer suplus in this market.

2 Background on the Medicare Market

2.1 History and Setting

The Medicare market insures over 65 million seniors and individuals with disabilities. Upon enrolling in Medicare, beneficiaries decide whether to enroll in Original Medicare (also called Fee-For-Service or Traditional Medicare) under the federal government or a Medicare Advantage (MA) plan from a private company. Original Medicare has essentially no restrictions on which doctors you can see, and it does not typically require prior authorization to cover procedures or see specialists. However, cost sharing is limited; there is a fairly large hospital deductible, and it only covers 80% of the cost of most appointments and procedures. This leaves beneficiaries responsible for the remaining 20% coinsurance, without an out-of-pocket maximum on annual costs. Medigap plans eliminate this financial "gap" in Original Medicare. These plans are sold by private insurers and offer some of the most comprehensive coverage available, substantially reducing or even eliminating altogether the cost sharing that would occur when seeking medical care. About 14 million people in the US today have a Medigap.

MA plans typically have more restrictions on care, with networks, required referrals, and prior authorization. However, MA plans also place limits on cost sharing with annual out-of-pocket maxima, and they often offer supplemental benefits like dental, vision, and hearing.

Not every beneficiary faces this gap unaided. Some retirees have supplemental coverage subsidized by a former employer or union, which fills the same cost-sharing role without a purchase decision; and some are dually eligible for Medicaid, which covers the cost sharing directly. In the 2023 Medicare Current Beneficiary Survey, 24% of beneficiaries have employer-sponsored coverage and 18% are dually eligible for Medicaid.

Since the passage of the 1990 Omnibus Budget Reconciliation Act (OBRA), the Medicare Supplement market has been composed of private firms offering standardized plans from a set menu (Freed et al. 2023). [2] These standard options are shown in Appendix Figure A1. [3] Medigap insurers are

2. Standardization admits one narrow exception. Section 9.1 of the NAIC Model Regulation permits an insurer to attach "new or innovative benefits" to an otherwise standardized plan, provided they do not alter or reduce any standardized benefit and do not cover outpatient prescription drugs. In practice, these are wellness extras sold alongside the plan, most commonly a gym or fitness membership (such as SilverSneakers) (National Association of Insurance Commissioners 2025). The NAIC filings flag such plans directly, and they are uncommon; less than 0.9% of life-years carry an innovative benefit.

3. This is in contrast to markets such as Medicare Advantage, where unusual plan benefits require assumptions about how

secondary payers; they must cover cost sharing if Original Medicare approves the expense, and they cannot cover cost sharing if Original Medicare denies their portion of the expense. There is very little discretion left to the insurer on what expenses to cover, which reduces the administrative burden of offering these plans. As the benefits have very little room to vary across insurers, we also expect essentially no differences in claims coverage or customer service by company. [4]

Medigap plans can carry high premiums, particularly when contrasted against MA. We calculate that average paid premiums for Medigaps exceed $200 dollars per month, while three quarters of enrollees in individual Medicare Advantage drug plans pay no premium beyond the Medicare Part B premium (Freed et al. 2026). Despite these high premiums, a focus group of insurance agents conducted by the Commonwealth Fund reports that most agents plan to enroll in Medigap themselves upon retirement, suggesting that expert consumers may value comprehensive coverage even at substantial monetary cost (Ali et al. 2021).

Because Medigap is the most comprehensive insurance product available in this market, adverse selection is of particular concern. To address this, federal regulations restrict Medicare beneficiaries to one primary access points to this market. Seniors are eligible to purchase any Medigap plan for 6 months when they turn 65 (or first get Part B). If they miss this enrollment window, or they want to switch their plan outside of it, most states require them to undergo medical underwriting. In practice, this requirment is often binding; we estimate that 58.9% of Medicare beneficiaries have health conditions that would lead them to be rejected or offered higher premiums by more than nine in ten insurers (Appendix E).

2.2 Legislation

There are limited federal consumer protections for Medigaps; beneficiaries are guaranteed access to a plan when they first join Medigap, and for certain market events (for example, moving out of a plan's service area, or a plan terminating its contract with CMS). However, the main federal regulations in this market are producer-facing. Insurers who close their Medigap plan to new enrollees cannot reenter the market for five years, and they must continue to cover the beneficiaries currently on their books. Insurers must also abide by a minimum loss ratio, spending at least 60% of what they collect in premiums on claims in the individual market. [5]

Since 2007, sixteen states have passed additional legislation intended to increase consumer choice within the Medigap market. Here, we define switching legislation as a rule that allows beneficiaries to switch out of their plan and get another Medigap policy at least annually. Figure 1 displays the states that have

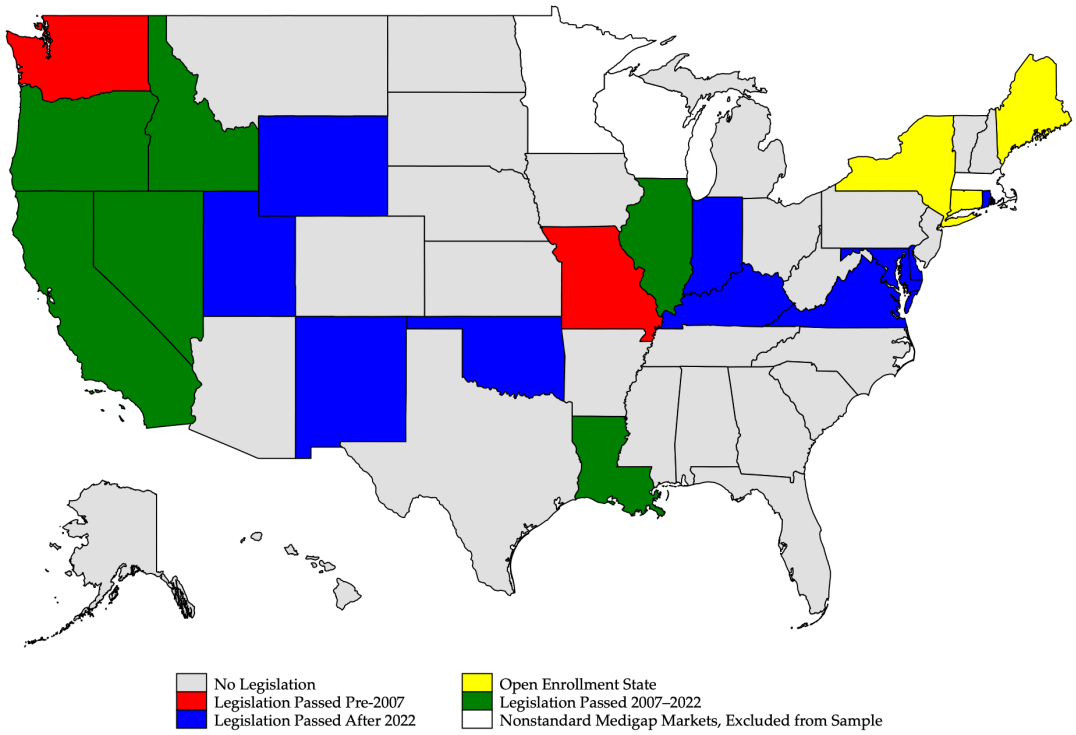

people value nonstandard plan features. For example, Humana's Healthy Options allowance gives enrollees in most of its Chronic Condition Special Needs Plans a preloaded spending card for over-the-counter items, which members with a qualifying chronic condition may also spend on food, utilities, phone service, and even rent or mortgage payments (Humana 2026). Ranking such a plan against a competitor requires assumtions on the value of some nonstandard benefits. Medigaps pose no such problem: within a plan letter, the benefit is identical across insurers.

4. Interviews with multiple insurance agents have confirmed that the law is applied this way in practice. The main exception would be that some plan letters have limited coverage of health events while traveling internationally.

5. The corresponding floor is 65% in the group market; we work primarily with the individual market throughout this paper. The floor is enforced across a projected 20-year life of the plan (NAIC 2000), and interviews with actuaries in this market suggest that it is not often binding. This floor is much lower than the 85% loss ratio enforced in many other health markets, such as Medicare Advantage and large-group commercial coverage under the Affordable Care Act (42 CFR 422.2410; 42 U.S.C. 300gg-18).

passed switching legislation by period. The six states in green (California (2009), Oregon (2013), Nevada (2022), Idaho (2022), Illinois (2022), and Louisiana (2022)) all passed switching legislation during our period of study, where we can observe at least three years before and after the passage. The remaining states, including the yellow open enrollment states, passed their legislation outside our period of observation. Open enrollment states require at least annual opportunities for people with no Medigap plan to purchase one without underwriting. This legislation provides more expansive access than switching legislation, but also may be more susceptible to adverse selection and delayed purchase of coverage.

Figure 1. Sixteen States Have Adopted Switching or Open-Enrollment Protections

Notes: Each state is classified by its Medigap switching/open-enrollment regime and the period of adoption. The six states shaded green adopted switching legislation inside our observation window and identify the event studies of Section 8.2. The yellow open-enrollment states and the remaining protected states adopted before the panel begins, so they are excluded from the control group rather than used as treated units. Massachusetts, Wisconsin, and Minnesota (shaded separately) are federal-waiver states that standardize Medigap under their own benefit designs rather than the lettered federal plans, and they are excluded from the sample entirely.

In a classical framework, these regulations would lower switching costs and should increase enrollment in less-expensive insurers while decreasing enrollment in the most expensive insurers. However, by making it easier for high-cost enrollees to stay in the market, they could drive up overall premiums. A more behavioral framework may suggest that offering consumers additional choice in a market where they make costly mistakes could allow for full or partial correction of these mistakes. To our knowledge, the efficacy of switching regulations in the Medigap market has never been studied.

2.3 Deadpooling

Interviews with insurance agents and actuaries specializing in this market report that large insurance companies have found a way to segment the market while complying with state regulations through a practice known as "deadpooling." This practice relies on high risk individuals being locked in to the first plan they buy, as they are unlikely to pass medical underwriting should they want to switch.

Why do states have regulations that lock seniors in to their plans? Adverse selection is a concern for insurers because Medigap coverage is so comprehensive. If consumers were able to acquire Medigap plans at any time, they may delay enrollment in this product until they expect large health expenditures, a practice Curto (2023) finds some evidence of. Limited federal guaranteed issue periods are intended to prevent this adverse selection problem. Enrollees outside of these limited guaranteed issue periods must pass medical underwriting in order to obtain Medigap coverage in most states.[6] While this restriction may help to keep the market stable for both insurers and seniors, one consequence is that seniors already in the Medigap market are usually not guaranteed the ability to shop for a new plan if their current coverage becomes unaffordable. For consumers who would not pass medical underwriting, this gives their initial insurer an effective monopoly over that consumer's business.

Aware of this risk, states regulate insurance companies to prevent them from exploiting this market power. One regulation requires companies to adhere to a loss ratio, which is intended to keep premiums down by limiting allowable premiums relative to costs (Frank and Milhaupt 2022), though this is not typically binding in practice.[7] States also limit the number of separate risk pools a company can have in the market at a given time to avoid sequestering high-risk seniors in expensive plans. Finally, if a company chooses to close a plan and stop accepting new enrollees, they cannot open another Medigap plan for five years in that market. These final regulations are enforced at the subsidiary level rather than the parent company level, so for large insurers with many subsidiaries, they are effectively not binding.[8]

Insurers respond to these regulations using deadpooling, a practice where insurance companies use subsidiaries to profit from the market power they possess over individuals. The mechanism does not require that the successor carry an unfamiliar name, and Appendix K finds no evidence that parents systematically reach for dissimilarly-named subsidiaries when they deadpool.[9] Here, we describe a

6. Interviews with agents and the interactive use of online screening tools offered by large insurers suggest that it is often quite restrictive. Our calculations comparing the MCBS to underwriting data for a limited subset of companies suggest around 70% of seniors would not pass underwriting; see Appendix E for the calculation.

7. Loss ratio regulations are enforced based on an actuary's projection of future premiums and claims rather than on a particular year's realized loss ratio, which makes loss ratio violations unlikely to be enforced (NAIC 2000). The individual- and group-market floors, and the contrast with the 0.85 standard applied in other health markets, are given in Section 2.2.

8. Executing this rotation does not require chartering an insurer. Because the reentry bar binds at the subsidiary level, a parent need only redeploy a subsidiary it already owns: 89.1% of successor blocks in our data are opened under an NAIC code that was already filing before the predecessor closed, and 95.6% among closures from 2010 onward, which are clear of the panel's opening years. For the 21.3% that were already selling Medigap in that same state, the marginal act is a rate and form filing. For the further 31.5% already selling Medigap in another state, the relevant instrument is the NAIC's Uniform Certificate of Authority Application (Expansion), an abbreviated filing that the Uniform States aim to clear within sixty days and that carries a $40 NAIC usage fee plus a modest state application fee (NAIC 2023). Statutory minimum capital and surplus for a foreign life and health insurer ranges from roughly $0.6 to $4 million across states (NAIC 2025), but this is capital held rather than expended, and a subsidiary already licensed in the state has met it. The concentration is stark: 1,837 successor blocks are supplied by just 91 distinct subsidiaries, a median of 10 blocks apiece, so whatever fixed cost a vehicle carries is amortized across many markets. Speed points the same way—25.0% of successors open in the closure year itself. Consistent with a low marginal cost, the median close-and-reopen chain is worth only $152,080 in present value and the twenty-fifth percentile $10,858, yet parents execute them.

9. Deadpooling is related to, but distinct from, the classic "invest-then-harvest" pattern, in which an insurer prices a cohort below cost early to attract enrollees and then raises premiums once they are locked in. Invest-then-harvest describes a price path

simple example of deadpooling. First, an insurance company enters the Medigap market under Subsidiary A. Some seniors join a Medigap plan operated by that subsidiary, and nominal premiums increase slowly every year to keep up with inflation and rising medical costs. Second, Subsidiary A stops accepting additional beneficiaries. Subsidiary A is not able to reenter the market for five years, so the parent company has Subsidiary B enter the market. Healthy and young Subsidiary A beneficiaries with low expected medical costs can undergo medical underwriting and switch to the new, cheaper plan. However, beneficiaries with health conditions or advanced age are unlikely to pass medical underwriting. This denies them access to a reduced premium. Next, sicker seniors become concentrated in closed plans, and insurance companies can cite higher healthcare costs as justification for further premium increases. As premiums rise, if a sick beneficiary is unable to afford their premium, they may end up unable to afford Medigap coverage entirely.

To prevent this, some states have enacted laws providing their residents with guaranteed switching periods. However, significant price dispersion persists even in states with such legislation, calling into question its efficacy. In New York, one of the states with the most flexible switching regulations, a 65 year old man could pay between $293 and $613 monthly for identical coverage in Medigap Plan G, depending on which company he buys it from (CMS 2025). The remainder of the paper documents how widespread deadpooling is in this market, quantifies the harm it imposes on locked-in enrollees, and evaluates whether the switching and open-enrollment regulations intended to curb it are effective.

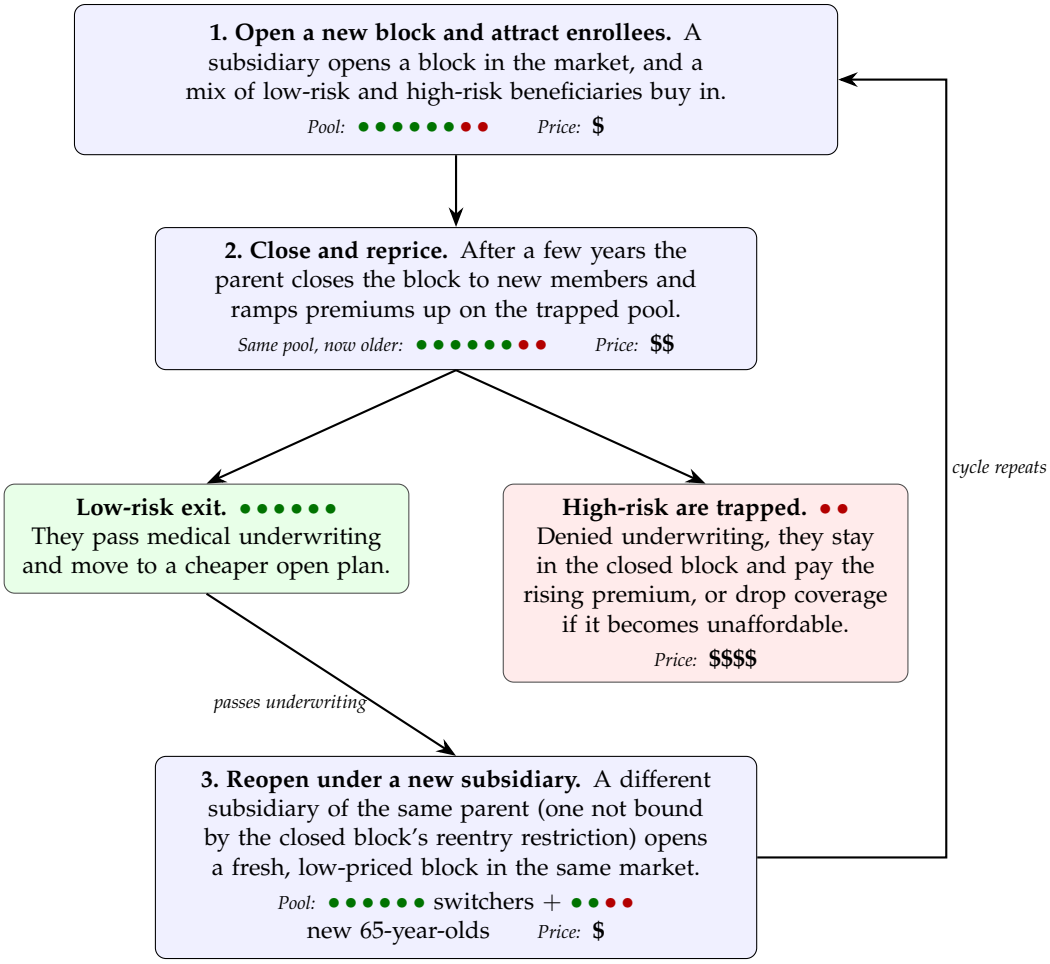

Because most parent companies in our data sell both products, a natural question is whether they deadpool more aggressively where they also run a large Medicare Advantage book, steering priced-out enrollees into their own alternative; Appendix J tests this and finds no stable relationship.

Deadpooling requires a parent company to take two coordinated actions. First, a subsidiary currently active in the market must close its plan to new members. Second, another subsidiary belonging to the same parent company must open a new plan in the same market. In most states, members of the first plan are unable to switch to a new plan without first passing rigorous medical underwriting, which they are unlikely to do. As a result, high-risk beneficiaries can become trapped in plans with rising premiums and may ultimately lose Medigap coverage if those premiums become unaffordable. By separating high- and low-cost beneficiaries into different plans, parent companies can raise premiums on high-cost enrollees without losing market share among low-cost enrollees. These incentives cause frequent plan closures in this market. Figure 2 summarizes the cycle.

Plan closures are pervasive. Following plans first observed before 2015 for a full ten years, nearly half of enrollees end up in a plan that has closed to new members (Appendix L). These patterns from a balanced panel are consistent with the broader data: 44.8% of the life-years in blocks we observe through 2020 are spent in plans we record closing. That figure is a conservative floor, since it counts only closures recorded in the filings and excludes blocks whose closure we impute; counting imputed closures as well raises it to 46.4%. Given the prevalence of plan closures, and assuming beneficiaries enroll in Medigap

within a single risk pool. Deadpooling is instead an organizational mechanism, in which a parent closes an old subsidiary and rotates a fresh one into the market, so that it can run the "harvest" phase on the trapped, high-cost enrollees left in the closed pool while simultaneously running the "invest" phase on the healthy switchers it attracts into the new pool.

Figure 2. The Deadpooling Cycle

Notes: The figure illustrates the deadpooling mechanism; the dots track a stylized pool of enrollees, green for low-risk and red for high-risk, and the dollar signs indicate the premium charged on the block. A parent opens a subsidiary block and attracts a mix of low-risk and high-risk enrollees (step 1), then closes the block to new members and raises premiums on the now-captive pool (step 2). Low-risk enrollees who can pass medical underwriting leave for cheaper open plans, while high-risk enrollees who are denied underwriting cannot leave. They remain in the closed block and pay the rising premium or drop Medigap coverage altogether. The parent then opens a fresh low-priced block in the same market through a *different* subsidiary (step 3), which is not subject to the closed block's reentry restriction, and the cycle repeats.

with the expectation of maintaining coverage as they age, these dynamics have the potential to affect a substantial share of the Medigap market.

Once a plan has been closed, how often does a new subsidiary open a new plan in the same market? About 38% of beneficiaries in plans that close experience parent company reentry within five years, most often in the exact year of closure; Appendix L reports the year-by-year timing. We define this reentry period to be within five years in accordance with the state regulations that prohibit reentry into the market within five years. These beneficiaries, in a plan whose parent company reenters within five years of their plan's closure, experience deadpooling. 17.6% of life-years through 2020 are spent in plans that deadpool.[10]

3 Related Literature

This paper contributes to four strands of research: consumer mistakes in complex insurance choice, the behavioral industrial-organization literature on firms that profit from consumer inattention, dynamic insurance markets with lock-in and open-ended pricing, and financialization in health care.

The first strand studies mistakes in consumer choice over complex health and financial decisions. It is well documented that consumers do not make optimal choices in many domains, including personal finance and health. Studies have identified dominated choices in 401(k) decisions (Choi, Laibson, and Madrian 2011), investment decisions (Mullainathan, Nöth, and Schoar 2011), health decisions (Baicker, Mullainathan, and Schwartzstein 2015), and selection of insurance policies (Bhargava, Loewenstein, and Sydnor 2017; Handel 2013). Choice of dominated insurance policies is especially prevalent among senior citizens making choices in the highly complex Medicare market (Handel and Kolstad 2015; Handel and Schwartzstein 2018; Abaluck and Gruber 2011, 2016; Ho, Hogan, and Scott Morton 2017; Ketcham, Lucarelli, and Powers 2015). This literature largely treats mistakes as a property of consumers—inattention, limited information, or bounded rationality. We add a supply-side counterpart: we show that the *market structure* in Medigap is organized so that firms can convert those mistakes into durable profits, and that the harm is concentrated on precisely the sick, immobile enrollees least able to correct a choice.

Most similar to this paper is Lin and Wildenbeest (2020), which estimates search costs in choosing a Medigap plan nonparametrically. They put the median search cost at $30, and the implication is that with search this cheap, the choice of dominated Medigap policies must be driven by information frictions and insurance agents rather than by the cost of looking.[11] We build on this work in two ways. First, we empirically examine regulations that should reduce switching costs, since they eliminate the detailed paperwork and medical appointments that medical underwriting typically requires. Second, we show that low measured search costs are not the whole story: even a shopper who pays nothing to

10. Both the numerator and the denominator of this share are restricted to 2020 and earlier. The restriction is necessary because identifying a deadpooling block requires observing whether the parent reopens within five years, so with the panel ending in 2025 a block closing after 2020 cannot yet be classified.

11. Maestas, Schroeder, and Goldman (2009), a working paper using a structural model, estimates a higher average search cost of $72 in the same market. We use the lower figure throughout, which is the conservative choice: the cheaper search is, the harder it is to explain dominated choices by search frictions alone.

search cannot act on a better price once medical underwriting bars them from switching, so the binding friction for the sickest enrollees is underwriting-based lock-in rather than search.

The second strand is the behavioral industrial-organization literature on firms that design products and price paths to exploit consumer inattention. Firms can shroud add-on prices (Gabaix and Laibson 2006) and steer inattentive consumers toward more expensive options (Heidhues, Köster, and Kőszegi 2023), so that competition does not compete away the resulting rents. Deadpooling is an instance of this mechanism realized through corporate structure rather than product features: an insurer advertises a low headline premium to attract enrollees, then raises prices on the locked-in pool while rotating a fresh low-priced subsidiary into the market to capture the next cohort. We contribute the first empirical documentation of this organizational form of inattention-exploitation in a regulated insurance market, and we quantify the rents it generates and the surplus it destroys.

One difference from that literature governs which remedies can work, and it is the reason we evaluate consumer-choice legislation as skeptically as we do. There, the rent is collected from consumers who do not attend to prices, so a consumer who does attend escapes it; the policy prescriptions that follow (disclosure, salience, defaults, and cheaper switching) all presume that the binding constraint is the consumer's attention. Here the rent is collected from consumers who have noticed the price and cannot act on it, because medical underwriting has closed the alternatives to them. Attention is then necessary but not sufficient, and a remedy addressed to it alone reaches only those enrollees who were never trapped in the first place. Figure 19 makes the point concrete: in the calibrated model a switching right alone removes 5% of the harm and raised attention alone 11%, but the two together remove 83%; they are complements, each relaxing a barrier the other leaves in place.

The third strand studies dynamic insurance markets in which pricing is open-ended and enrollees become locked in as their health deteriorates. When switching is costly, incumbents can raise prices on a captured base without losing it to competitors (Farrell and Klemperer 2007), and dynamic insurance contracts respond to this by front-loading premiums—charging young, healthy enrollees above cost to fund a commitment against later reclassification, as Hendel and Lizzeri (2003) document in life insurance. Ghili et al. (2024) characterize the optimal such contract under one-sided commitment, in which the insurer is bound to a price path and the consumer remains free to leave, and show that it removes most of the welfare cost of reclassification risk for enrollees who arrive in good health. Medigap inverts that asymmetry. Underwriting at switching closes the consumer's outside option precisely as their health deteriorates, so the commitment runs the wrong way: the enrollee is bound and the insurer is not. Policies are guaranteed renewable, but premiums are set at the block level and may be raised at will, so the market supplies the lock-in that makes a long-term contract feasible without the price commitment that makes one valuable. Deadpooling is what that configuration produces. Health insurance sits at the opposite pole: without such commitment, enrollees face reclassification risk that locks them into a plan once they fall ill (Atal 2019; Handel, Hendel, and Whinston 2015), and firms exploit the resulting inertia to raise prices on incumbents, a pattern known as "invest-then-harvest" pricing (Ericson 2014). A related literature shows how these dynamics can unravel a pool entirely:

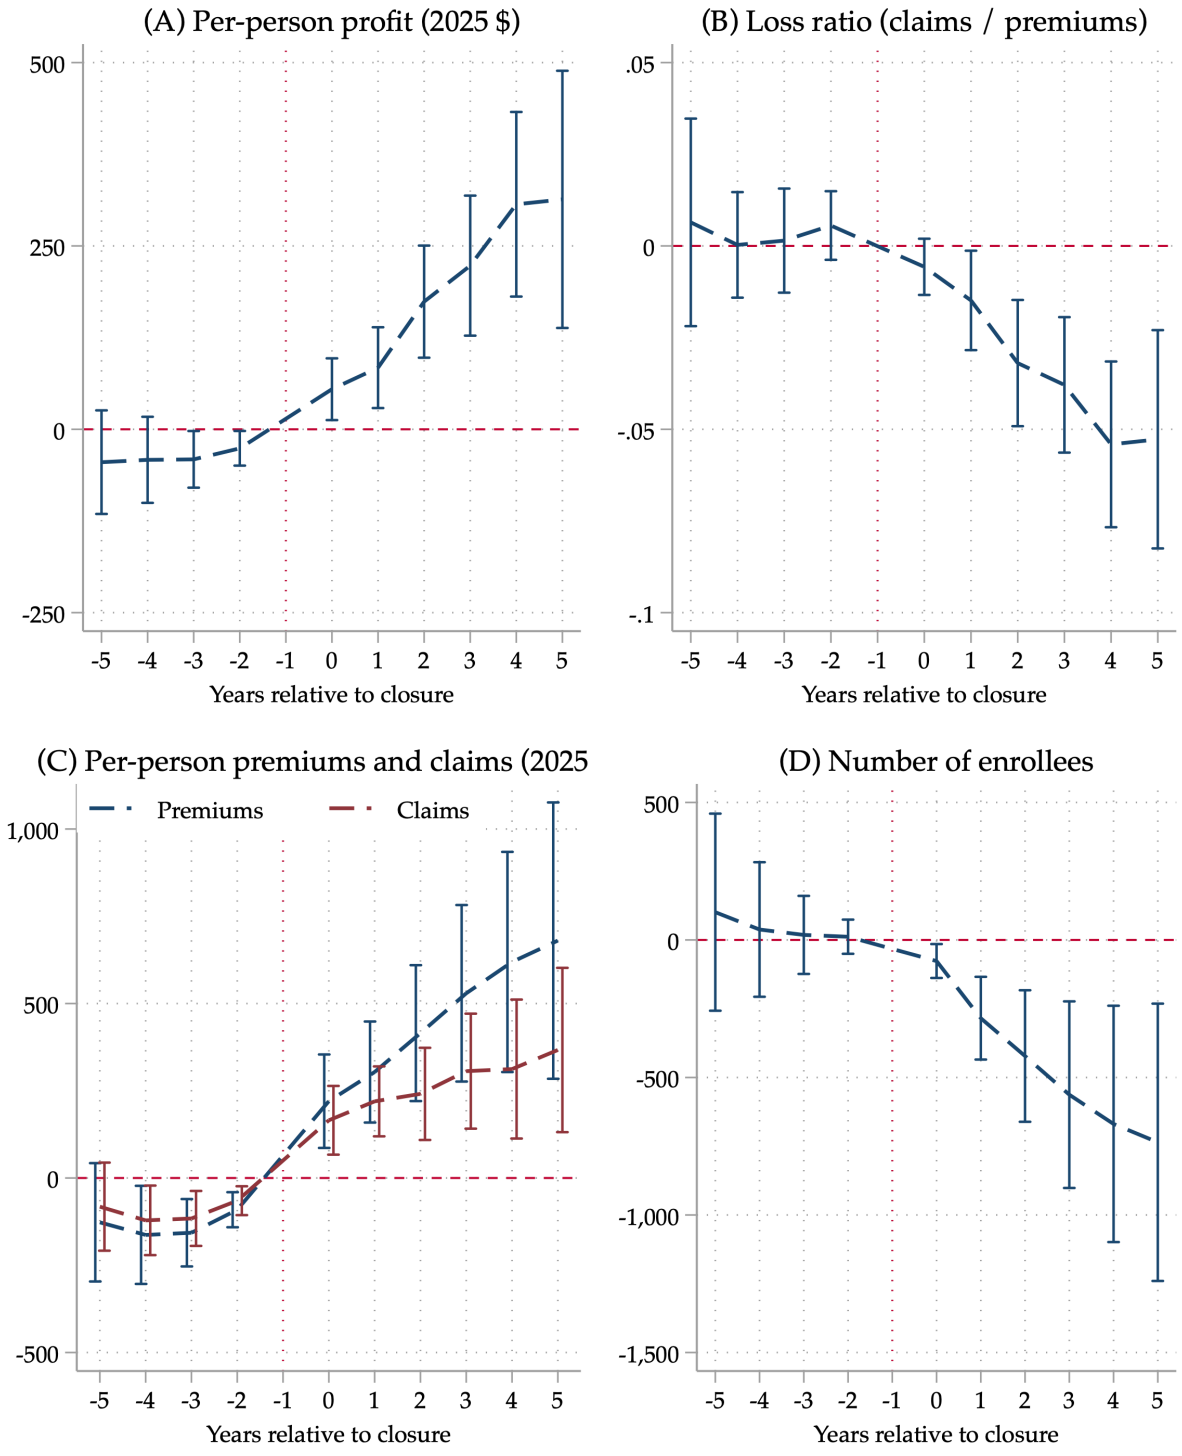

adverse selection can send a plan into a premium "death spiral" as healthy enrollees leave (Cutler and Reber 1998), and the timing of claims relative to enrollment generates ex post adverse selection even absent private information at entry (Cabral 2017). Deadpooling is a supply-side counterpart to these forces. Rather than a single pool front-loading or unraveling on its own, an insurer *deliberately* closes a pool to trigger the harvest phase on the enrollees who cannot pass underwriting, while opening a fresh, low-priced subsidiary to capture the healthy switchers. The death spiral becomes a profit center rather than an equilibrium failure the insurer suffers. Put another way, in these accounts reclassification is a risk the market fails to insure against, arising because no one can commit to future prices (Handel, Hendel, and Whinston 2015); here it is an event a firm produces strategically, on a date of its choosing.

That distinction is testable rather than rhetorical, and separating the two is what the empirical sections do. If a closed pool's premium merely tracked the cost of the pool it retained, premiums and claims would rise together and the ratio between them would be unchanged; deliberate extraction instead separates them. They separate here: premiums outrun claims and the loss ratio falls (Table 2, Figure 3). And the separation follows the firm's decision rather than the aging of the pool, since blocks of the same plan letters that firms left open until MACRA closed them by statute show neither movement (Section 6.3).

A body of work studies these forces in the Medigap market itself, where pricing and selection are directly regulated. Curto (2023) finds that community-rating regulations, which bar pricing on age, sex, and health, delay enrollment and induce adverse selection. Comparing beneficiaries living within 25 miles of borders between three community-rated states, which pair uniform premiums with guaranteed issue, and six states guaranteeing only renewal, she finds community rating associated with Medigap enrollment lower by 9.70 percentage points, purchase delayed by 1.08 years, and annual premiums higher by $276. Elsewhere in this literature, Starc (2014) shows that insurers exercise substantial market power over Medigap enrollees despite standardized benefits; and Fang, Keane, and Silverman (2008) document advantageous selection in this market. Curto studies pricing regulation over an earlier window (2006–2010), when Part D was new and Medicare Advantage held a much smaller share than today. We differ in mechanism and object of study: rather than a within-pool price path or a static selection pattern, we identify a *cross-subsidiary* strategy in which the same parent runs the harvest phase on a closed pool and the invest phase on an open one simultaneously, and we evaluate the switching and open-enrollment regulations designed to interrupt it—regulations whose efficacy, to our knowledge, has not previously been studied.

The fourth strand studies regulatory arbitrage through corporate structure: firms that satisfy a rule at each of the legal entities it binds while defeating it at the level of the enterprise that actually decides. Koijen and Yogo (2016) document the clearest insurance case, in which life insurers cede liabilities to reinsurers they themselves own in more lightly regulated jurisdictions, so that the risk never leaves the group while the capital the group must hold against it falls. The common structure is a mismatch of units: the rule is written for a licensed entity, the decision is taken by a parent that owns many of them, and compliance entity by entity is perfectly consistent with evasion in aggregate. Deadpooling is that

Figure 3. Profit Rises and the Loss Ratio Falls After Closure, as Premiums Outrun Claims and Enrollment Drains

Notes: Panels are per-enrollee profit (A), the loss ratio (B), per-enrollee premiums and claims together (C), and the number of enrollees (D). Each panel plots the Callaway-Sant'Anna (2021) ATT of plan closure by event time, aggregated across cohorts and normalized to zero at event time -1 (the year before closure). Never-treated (never-closing) plans serve as the control group, and the doubly-robust regression adjustment includes state and plan-type (standardized plan letter) controls. 95% confidence intervals use NAIC-clustered standard errors. Dollar outcomes are adjusted to 2025 dollars. Panel C puts premiums and claims on one axis because they are the same units on the same sample and specification, so the widening gap between them is exactly the profit in panel A and the fall in panel B. Panels A through C are enrollment-weighted; panel D is not, because its outcome *is* enrollment and weighting by lives would up-weight the very blocks whose size is being measured. Panel A is drawn on a fixed -250 to 500 scale. Joint pre-trend tests (leads $t-6$ to $t-2$, $t-1$ the base period): tests reject at the 5% level for premiums, $p = 0.016$; claims, $p = 0.042$; all other pre-trend tests in this figure are not significant at the 5% level (profit, $p = 0.150$; the loss ratio, $p = 0.235$; enrollment, $p = 0.938$).

mismatch in a consumer market. Each regulation meant to contain it (the five-year bar on reentry, the limit on how many risk pools a company may run at once, the minimum loss ratio) binds a subsidiary, while the decision to close one block and open another belongs to the parent.

What the entity boundary is used *for* here differs from those cases, and the difference is the contribution we intend. In the arbitrage documented elsewhere, corporate separation relocates risk, income, or liability so that a rule applies differently to the firm, and the party who bears the consequence is the regulator or the public balance sheet. In deadpooling it relocates nothing. It changes what a consumer may buy: one insurer may not offer the same standardized plan letter at two prices, but two subsidiaries of a single parent may, and the health test that sorts enrollees between them settles which price each of them pays. Corporate structure is the instrument that makes a two-tier price list lawful, and the party who bears the consequence is the enrollee.

This bears in turn on consolidation in the market we study, which has been substantial. Deadpooling requires a stable of subsidiaries to execute, so it is available disproportionately to large, consolidated parents, and we find it concentrated among them. Consolidation here therefore matters for more than market power in the conventional sense: a parent with many subsidiaries is a parent for whom the reentry rule does not bind. The adjacent literature on financialization in health care has studied mostly the provider side, documenting that consolidation and cost-cutting worsen patient care, raise costs, and widen gaps in access to care and insurance (Kirby and Kaneda 2010; Koch, Wendling, and Wilson 2018; Blumenthal 2023); we add an insurer-side case in which the harm runs through the prices charged to enrollees who cannot leave.

4 Data

We construct a Medigap pricing and plan choice dataset from 2006–2025 by combining four sources: (i) plan enrollment, premium, and claims filings from the NAIC; (ii) annual parent-to-subsidiary ownership mappings, also from the NAIC; (iii) quoted-rate data from CSG Actuarial, the private consulting firm that maintains the pricing data underlying the government's Medicare.gov plan finder; and (iv) a Medigap shopping-behavior module we fielded on the Understanding America Study (UAS). The NAIC filings let us document deadpooling, a firm pricing phenomenon no other paper has been able to quantify, and provide the first statistics on how common it is. CSG rates let us separate quoted prices from realized premiums, which are affected by selection into coverage. The UAS module measures how actively enrollees shop, which disciplines the demand side of our model. We also get supplemental and contextual information from the Medicare Current Beneficiary Survey and a survey of agents and brokers who enroll seniors in Medicare products.

4.1 NAIC Plan Data

The NAIC insurance filings contain information about the number of beneficiaries covered by each plan at the policy-group status-insurer-state-year level from 2006–2025. These data were purchased from

Mark Farrah Associates. They also contain information on total premiums collected and total claims paid, and some plan enrollment characteristics. This dataset is where we obtain the dates when plans were first approved to join the market and when plans were closed or withdrawn from the market.[12] In this analysis, we focus on standardized plans in the individual market. To this end, we exclude employer plans, as no particular employer plan is in the choice set of the average enrollee. We also exclude Medicare SELECT plans, as they incorporate provider network restrictions.

We link plans across years using the NAIC code of the issuing company, the state, the plan letter, and the group status of the plan. The unit of observation in the resulting panel is a *block* (a subsidiary $\times$ state $\times$ plan-letter cell) observed annually. Full information on cleaning this dataset is reported in Appendix M.

From the raw filings we construct the variables used throughout the paper. The financial variables are per-enrollee premium (total premiums collected divided by covered lives), per-enrollee claims (total claims paid divided by covered lives), per-enrollee profit (total premium minus total claims, divided by covered lives), and the loss ratio (total claims over total premiums; the share of premiums spend on medical costs). All dollar figures are inflation adjusted to January 2025 dollars. We then construct block age (years since the plan's first approval) and an indicator for whether the block is open or closed to new enrollment in each year. Finally, we construct our key object, a *deadpooling* flag, equal to one if the block ever closes and the parent opens a successor subsidiary in the exact same market within five years of closure.

4.2 Subsidiary Mapping Data

We use parent to subsidiary mappings from the NAIC for every year of the panel, 2006 to 2025. We link parents to subsidiary codes each year in order to ensure smaller companies that change parent ownership over our period are linked to their correct parents each year. NAIC codes who do not merge to a parent from this list are considered to be their own parent. Closure and reentry are regulated at the subsidiary level, so a parent with many subsidiaries can close one block and open another without violating the regulation. Appendix M describes which edition of the mapping we use and how NAIC codes are matched to years.

4.3 CSG Pricing Data

We supplement the NAIC filings with quoted-rate data from CSG Actuarial, the private firm that maintains the pricing information underlying the government's Medicare.gov plan finder. We observe these data from 2013 to 2025, but use them only from 2014 on, because the 2013 vintage is unreliable. They are recorded at the company $\times$ ZIP code $\times$ plan-letter $\times$ individual-pricing level. An *individual pricing* cell is defined by the applicant characteristics on which a carrier is permitted to vary its quote for

12. Plan closure refers to a pool that no longer accepts new members, but continues to insure existing members who pay their premiums. This does not trigger a special enrollment period for members. Plan withdrawal refers to an insurer leaving a market entirely. Withdrawn plans do not continue to insure existing customers in that market, and plan withdrawal would trigger a special enrollment period for beneficiaries losing their coverage.

a given plan letter: age, gender, tobacco use, and whether the applicant qualifies for a household or couple discount. This data also provides the plan's rating methodology (issue-age, attained-age, or community-rated). This data is disctinct from the NAIC data on premiums collected, as CSG records the quoted price a new applicant would be offered, whereas the NAIC records the average premium paid by the existing pool who decided to purchase coverage. From these data we construct quoted rates at different ages, the age-rate profile and implied age multipliers used to calibrate the model, and the cheapest available quote in each market. We assume beneficiaries are nonsmokers and do not incorporate discounts. We also omit plans with nonstandard benefits. Appendix M contians additional details on how this dataset is cleaned.

A separate CSG file records the rate changes carriers file on blocks that have already closed. Each row is a carrier $\times$ NAIC subsidiary $\times$ state $\times$ effective date $\times$ plan letter, and increases changes all enrollees' rates proportionally. Because these are the prices charged to enrollees who can no longer be quoted a new rate, they measure something the quoted-rate feed cannot: what happens to a premium once the only people paying it are the ones who could not leave. Not all states require companies to file rate increases in this way, so this closed-rate data covers 38 states.

4.4 UAS Shopping Module

To measure how actively Medigap enrollees shop, we fielded a custom module on the Understanding America Study (UAS), a nationally representative internet panel run by the University of Southern California's Dornsife Center for Economic and Social Research. Our module (fielded July 2025) asks Medicare beneficiaries about their Medigap enrollment, the number of insurance agents they consulted, and whether they have ever switched plans. It is linked to the panel's standard demographic file.

4.5 MCBS and Medigap Underwriting Criteria

Whether a senior can leave a closed block depends on whether they would pass medical underwriting, which to our knowledge no existing data source quantifies. We build our estimate of underwriting approval from two sources. The first is the public use file of the Medicare Current Beneficiary Survey (MCBS), a nationally representative survey of Medicare beneficiaries reporting diagnosed conditions, coverage type, and spending. We use this data both for condition prevalence and for the age gradients in claims. The second is the set of underwriting criteria carriers apply, which we collect from CSG Actuarial. This data gives the conditions and lookback windows on which an application is flagged for medical underwriting, triggering higher rates or denial of coverage. We match health conditions among Medicare beneficiaries from the MCBS to the conditions used for underwriting in the CSG underwriting criteria datato estimate the share of a closing block's enrollees who would be approved elsewhere at competitive rates. Appendix E contains additional details on the CSG underwriting data and the crosswalk to the MCBS conditions.

4.6 Medicare Agent Survey

The data above describe deadpooling from the insurer's side. Because agents are the intermediaries who place seniors into plans and who see the closed blocks their clients sit on, we also fielded a survey of licensed Medicare insurance agents. We ask agents how they advise clients whose block has closed, and how they advise clients in different shopping scenarios. We report the instrument and some descriptive results in Appendix N.

5 Empirical Strategy

Our primary estimation strategy looks at the impact of the closure event. We compare plans that deadpool to a control group of plans that remain open in the market. Because blocks close in different years, this is a staggered-adoption design, and our primary estimator is Callaway and Sant'Anna (2021). This section states the specification and describes how we test the identifying assumption. Alternative specifications for our main results are reported in Appendix P.

5.1 Setup and estimand

We index blocks by i and calendar years by t. Let G_i denote the year in which block i closes to new enrollment, setting $G_i = \infty$ for a block that never closes. We write $Y_{it}(1)$ and $Y_{it}(0)$ for the potential outcomes with and without closure, where Y is per-enrollee premium, claims, profit, or the loss ratio.

A block *deadpools* only if its parent also reopens, so we define the deadpooling indicator:

$$DP_i = \underbrace{\mathbf{1}\{G_i < \infty\}}_{i \text{ ever closes}} \times \underbrace{\mathbf{1}\left\{\begin{array}{c} i\text{'s parent opens a block in the same state} \times \text{plan-letter} \\ \times \text{ group market during } [\,G_i,\ G_i + 5\,] \end{array}\right\}}_{\text{parent reopens in the same market within five years}}. \tag{1}$$

The five-year window was selected to align with state regulations that bar reentry into a market within five years of plan exit. A block that closes and is never replaced is an ordinary closure, and a parent that opens a block without closing one is an ordinary entrant; only a closure followed by same-market reentry inside the window counts as deadpooling. Plan closure is our treatment event for deadpooling plans, and plans that never close are our control group. We report results for nondeadpooling closures, $\{G_i = g,\ DP_i = 0\}$ in Appendix P.2.

The building block of each estimation is the group-time average treatment effect

$$\mathrm{ATT}(g,t) = \mathbb{E}[\,Y_{it}(1) - Y_{it}(0) \mid G_i = g\,], \tag{2}$$

the causal effect on outcomes in calendar year t of plan closure in year g. Identification uses *never-closing* blocks as the comparison group, under conditional parallel trends: for $t \geq g$,

$$\mathbb{E}\big[\,Y_{it}(0) - Y_{i,g-1}(0) \mid G_i = g,\ X_i\,\big] = \mathbb{E}\big[\,Y_{it}(0) - Y_{i,g-1}(0) \mid G_i = \infty,\ X_i\,\big], \tag{3}$$

where X_i is a vector of time-invariant controls.

The tables report the overall aggregation across years weighted by enrollment, $\theta = \sum_g \sum_{t \geq g} w_{gt} \, \mathrm{ATT}(g,t)$. The figures report the event-time path $\theta(e)$, $e = t - g$, normalized to the year before closure such that $\theta(-1) = 0$ as in the closure design.

We cluster standard errors at the NAIC insurer level throughout, as we find empirical evidence of closure occurring subsidiary-wide (Appendix G). We report results clustered at the parent and at the block level in Appendix P.3. We weight results by enrollment unless otherwise reported to represent the experience of an average enrollee-year.

5.2 Legislative analysis

We estimate the effect of switching legislation using the same Callaway–Sant'Anna estimator as above, with the unit and the timing variables redefined to match the level at which the policy is assigned. Treatment is assigned at the state $\times$ year level, which is coarser than the block $\times$ year unit used above. We collapse the panel to state $\times$ plan-letter $\times$ year, taking enrollment-weighted cell means, instead of running the regression on blocks as the closure design does. This looks at the total prevalence of outcomes in the market, rather than restricting identification to plans in the market both before and after the regulation is passed. We index these cells by j. Let$s(j)$ be the state of cell j, and let A_s denote the year in which state s adopts a switching rule, with $A_s = \infty$ for a state that never adopts. The group-time average treatment effect is

$$\mathrm{ATT}^{\mathrm{leg}}(a,t) \;=\; \mathbb{E}\Big[\, Y_{jt}(1) - Y_{jt}(0) \;\Big|\; A_{s(j)} = a \,\Big]. \tag{4}$$

This is the causal effect on outcomes in calendar year t of switching law passage in year a. The control group is never-adopting states, with the conditional parallel trends assumtion

$$\mathbb{E}\Big[\, Y_{jt}(0) - Y_{j,a-1}(0) \mid A_{s(j)} = a,\, X_j \,\Big] \;=\; \mathbb{E}\Big[\, Y_{jt}(0) - Y_{j,a-1}(0) \mid A_{s(j)} = \infty,\, X_j \,\Big], \tag{5}$$

where X_j is an optional vector of time-invariant controls. States with switching rights or open-enrollment rules that predate our panel are excluded from the control group. Standard errors are clustered by state, the level at which the law is assigned. We observe six treated states (Figure 1 maps each state's regime), so the single-state columns of Table 6 are wide. We weight results by enrollment unless otherwise reported to represent the experience of an average enrollee-year.

The tables report the overall aggregation across passage years such that $\theta^{\mathrm{leg}} = \sum_a \sum_{t \geq a} w_{at} \, \mathrm{ATT}^{\mathrm{leg}}(a,t)$. The figures display the event-time paths $\theta^{\mathrm{leg}}(e)$, $e = t - a$. normalized to the year before closure such that $\theta^{\mathrm{leg}}(-1) = 0$.

5.3 Testing parallel trends

Assumption (3) requires that blocks which close would have followed parallel average paths to control blocks in the absence of closure once the covariates X_i are held fixed. This is untestable for $t \geq g$, but we can test whether this is true before closure. We aggregate the pre-treatment cells to event time and test

$$H_0 : \theta(-6) = \theta(-5) = \theta(-4) = \theta(-3) = \theta(-2) = 0 \tag{6}$$

jointly by a Wald test, where $\theta(-1) \equiv 0$ is the base period against which every event-time effect is measured.

Whether pre-trends hold depends on the outcome. For deadpooling closers, premiums and claims reject at the five percent level in every specification, including the fully adjusted one ($p = 0.004$ and $p = 0.025$), while profit and the loss ratio do not ($p = 0.188$ and $p = 0.260$). For non-deadpooling closers, no outcome rejects in the fully adjusted specification. Table A12 in Appendix P.1 reports every test.

The testable implication of (5) is the analogue of (6), over the same five leads,

$$H_0 : \theta^{\text{leg}}(-6) = \theta^{\text{leg}}(-5) = \theta^{\text{leg}}(-4) = \theta^{\text{leg}}(-3) = \theta^{\text{leg}}(-2) = 0. \tag{7}$$

California adopted its switching rule in 2009 and our panel begins in 2006, so it contributes only to the leads at $t - 3$ and $t - 2$; we therefore also report the test with California excluded, in which every remaining adopter has all five pre-years. With six treated states the state-clustered covariance is poorly conditioned, so we report the test two ways: against that covariance, and by randomization inference, reassigning the observed adoption years across the eligible states 199 times and recomputing the Wald statistic each time. On the pooled specification the clustered test rejects for premiums ($p = 0.000$), claims ($p = 0.003$), profit ($p = 0.037$), and the loss ratio ($p = 0.024$), but not for the CSG quoted-price index ($p = 0.496$) or the deadpooling share ($p = 0.848$). Under randomization inference no outcome rejects at the 5% level (premiums $p = 0.095$, claims $p = 0.250$, profit $p = 0.405$, loss ratio $p = 0.455$). Excluding California, the clustered test also rejects for the deadpooling share ($p = 0.003$), whose randomization-inference p is 0.345.

6 Firm Response to Regulation: Deadpooling

6.1 Summary Statistics

Table 1 reports summary statistics for our panel, reporting statistics for the full market, deadpooling plans split before and after closure, all non-deadpooling plans, and plans that never close. We observe 228 parent companies in our sample who operate over 17,000 risk pools. 107 of these parent companies run a block that meets the definition of deadpooling during our sample period. This table does not adjust for differences in state legislative environments or for differences in plan letter composition.

In the CSG panel, mean rates for plans that will deadpool but are still open look relatively similar in

quoted premiums to nondeadpooling plans across multiple ages. Per-person collected premiums in the Mark Farrah data are much lower for open deadpooling plans that for plans that do not deadpool. This partially reflects differences in pool composition, as enrollees in new risk pools are typically younger and healthier than in more established pools. Per-person claims are much lower for open deadpooling plans than for plans that do not deadpool. Per-person profits are similar in magnitude for plans that do not deadpool and open deadpooling plans.

Once deadpooling plans close, their premiums are hundreds of dollars per year higher than in plans that do not close in the quoted-price CSG data. The Mark Farrah data paints a picture of a risk pools that have deteriorated, with per-person claims much higher than those in nondeadpooling plans. Deadpooling plans spend a slightly lower share of their collected premiums on claims both before and after closure. Per-person profits are high higher in dollar terms after closure for deadpooling plans.

These comparisons are descriptive. The columns differ in state, plan letter, block age, and calendar year as well as in closure status, so the gaps in Table 1 are not the effect of closing a block. The rest of this section asks whether deadpooling pays the parent that does it (Section 6.2) and whether the repricing follows the firm's choice to close rather than closure as such, using a statutory closure the firm did not choose (Section 6.3). Section 7 then isolates the closure itself, comparing each closing block with never-closing blocks in event time.

6.2 Is Deadpooling Profitable?

At the parent level, deadpooling involves two books of business, one an older, closed risk pool, and the other a new, open pool. While firms earn additional profit on the enrollees who remain in the closed pool, they also lose many enrollees from that pool, making the net effect on profit ambiguous. In this section, we explore how often deadpooling is more profitable than leaving the pool open. We compare everything a parent earned in a market (a state and plan letter) over the ten years after its first deadpooling closure there with what the same book of business would have earned had the parent not deadpooled.

The counterfactual holds the book's market share at its level in the closure year, so the book grows or shrinks with the market rather than only losing enrollees. It keeps the book's own premium level before closure but moves it with the premiums of never-closing blocks in the same state, plan letter and year, so the parent's repricing after closure never enters the counterfactual; and it earns the margin per premium dollar of those never-closing blocks. A counterfactual built this way can miss for reasons that have nothing to do with deadpooling, so we run the same calculation for every parent-market book that never deadpools, reweighted to the deadpoolers' start years, and report how much more the deadpooling books beat their counterfactual than these books beat theirs. If the counterfactual misses by the same proportion for every book, this comparison removes the miss.

Formally, for a book b in market m (a state and plan letter) whose first deadpooling closure is in year t_0,

Table 1. Premiums Rise After Closure for Deadpooling Blocks

	Means by block status			
	Full sample	Never close	Open, DP	Closed, DP
CSG: Quoted rates, 2014–2025				
Annual rate, age 65	$2,613	$2,578	$2,548	$2,809
Annual rate, age 70	$3,031	$2,979	$2,946	$3,221
Annual rate, age 75	$3,404	$3,289	$3,363	$3,729
Annual rate, age 80	$3,728	$3,562	$3,725	$4,172
Annual rate, age 85	$3,953	$3,768	$4,056	$4,553
NAIC: Collected premiums, 2006–2025				
Mean per-person profit	$625	$543	$629	$881
Mean loss ratio	0.80	0.82	0.77	0.78
Mean per-person premium	$2,976	$2,852	$2,504	$3,507
Mean per-person claims	$2,351	$2,309	$1,875	$2,626
Mean enrollment	813	1,398	723	338
Plan-block-years	186,561	68,703	11,767	37,714
Unique blocks	17,101	6,658	3,166	4,768
Parent companies	228	141	107	124

Notes: Premiums, claims, and profits are per enrollee and enrollment-weighted. Dollar figures are in January 2025 dollars. The loss ratio is total claims divided by total premiums, and represents the share of premiums collected that are spent on medical claims. Profits are defined as premiums minus claims. "Open, DP" and "Closed, DP" are the pre- and post-closure block-years of a *deadpooling* block. "Never close" is the control group of the closure event studies, blocks that never close to new enrollment. Identifying a successor requires five years of post-closure data and the panel ends in 2025, so closers are restricted to those closing in or before 2020; never-closing blocks are retained in full. Unique blocks are counted within each column, so a deadpooling block observed both before and after closure appears in both DP columns, and blocks already closed when first observed appear only in "Closed, DP". The 4,768 deadpooling and 12,333 non-deadpooling blocks together make up the 17,101 of the full sample. This table pools all regulatory regimes; Appendix O repeats every row separately for open enrollment, annual switching window, and no protections states.

The NAIC filings cover 2006–2025 in 48 states (every state and the District of Columbia except the waiver states Massachusetts, Minnesota, and Wisconsin). CSG quotes cover all 48 of those states; we use them from 2014 to 2025 and do not use the 2013 vintage, so the CSG rows describe block-years from 2014 on. Over those years, an own-year CSG quote exists for 42.3% of the table's block-years, holding 78.0% of covered lives; counting the renewal prices described below, a CSG price exists for 49.0% of block-years and 82.4% of lives.

The NAIC rows reflect who holds the block, while a CSG row is the annual rate published for one fixed hypothetical non-smoking applicant of the stated age, taken as the equal-weight mean of the male and female quote. We average the CSG rate evenly over ZIP codes within a state and across companies by weighting with covered lives from the NAIC. Reading down the ages traces the age gradient in posted prices holding the block mix fixed. A closed block admits no new applicant, so for a closed block-year that CSG no longer quotes, in any column, the entry is the schedule its incumbents renew on: the block's last observed CSG quote chained forward by the closed-block rate increases the carrier filed with the state. Where a closed block is still quoted in that year, its own quote is used. This renewal price reaches 9,082 of 25,310 deadpooled closed block-years since 2014 (35.9%, or 62.6% of the lives in them); a block that neither carries a quote nor appears in the closed-block filing file contributes nothing to the cell. The pre- and post-closure CSG cells draw on nearly the same blocks: of the lives in deadpooling blocks priced before closure, 2.7% are in blocks with no price after closure. In the other direction, 24.9% of the priced post-closure lives are in blocks with no priced pre-closure year since 2014.

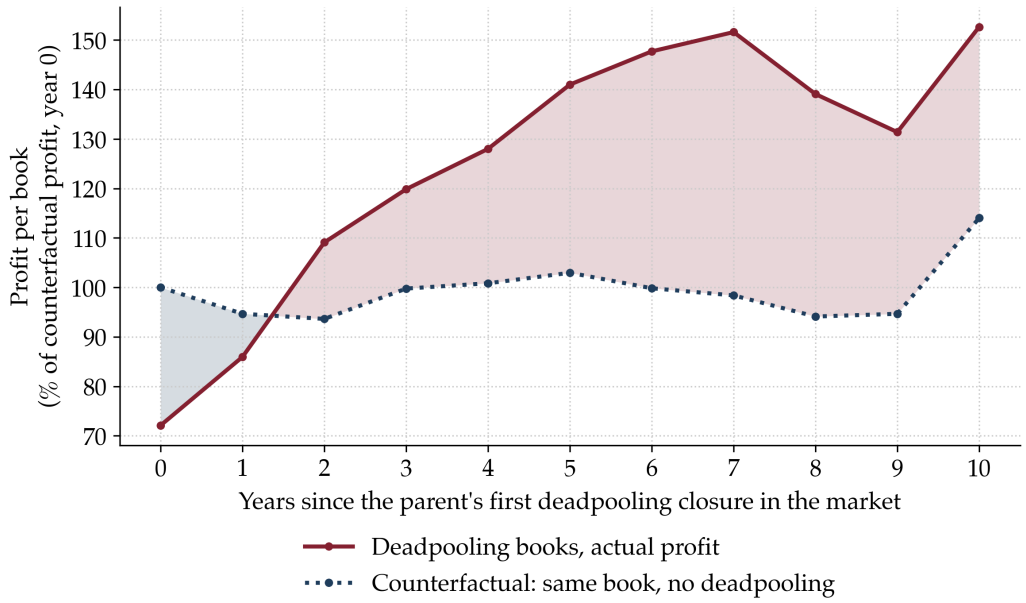

counterfactual profit in year $t = t_0 + k$ is

$$\tilde{\pi}_{bt} = \underbrace{s_b\, L_{mt}}_{\text{enrollees}} \times \underbrace{\bar{P}_b \frac{P^N_{mt}}{\bar{P}^N_m}}_{\text{premium per enrollee}} \times \underbrace{\mu^N_{mt}}_{\text{margin}}, \tag{8}$$

where s_b is the book's share of market enrollment in t_0, L_{mt} is market enrollment in year t, $\bar{P}_b$ is the book's premium per enrollee over the five years before t_0, P^N_{mt} is the premium per enrollee of never-closing blocks in the market and year and $\bar{P}^N_m$ its average over the same five pre-closure years, and μ^N_{mt} is never-closing blocks' profit per premium dollar in the market and year (pooled over states, and then over letters, when a market has fewer than five never-closing blocks). The gain from deadpooling is the book's actual profit π_{bt} minus $\tilde{\pi}_{bt}$, summed over $k = 0, \ldots, 10$ and discounted to t_0 at 5%.

Figure 4 plots actual and counterfactual profit, averaged over the 1,132 deadpooling books observed for the full ten years. Deadpooling books earn less than the counterfactual in the closure year and the year after, as the closed block sheds enrollees, and more from the second year on; the cumulative gain, discounted at 5%, turns positive 4 years after closure. Over the full ten years, for the 909 deadpooling books of 56 parents whose first closure falls in 2008–2015, deadpooling books earn 18.9% more than the counterfactual implies, relative to books that never deadpool. The size of the gain depends on how the counterfactual margin is measured, ranging from −9.3% to 18.9% across ways of measuring the counterfactual margin. Part of the gain comes through market share: deadpooling books end the window with 1.28 times the enrollment their starting share implies, against 1.11 for books that never deadpool.

Figure 4. Deadpooling Books' Profit Against the Counterfactual

Notes: Mean profit (premiums minus claims) per parent × state × plan-letter book, undiscounted, for the 1,132 deadpooling books observed for all ten years after the parent's first deadpooling closure in the market (year 0), indexed so that the counterfactual's year-0 profit equals 100. Solid: actual profit. Dotted: the counterfactual of equation (8) with never-closing blocks' margin rate. Shading: blue where actual profit is below the counterfactual, red where it is above.

6.3 Deadpooling Is a Choice: A Natural Experiment in Plan Closure

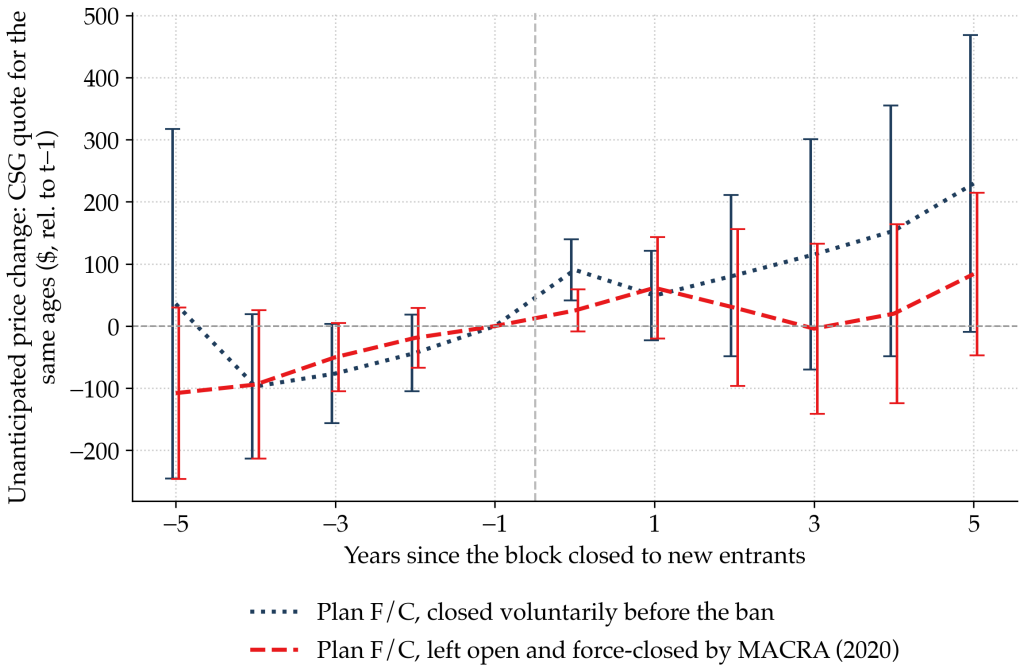

Deadpooling hinges on a firm's *choice* to close a block and reprice the pool it retains. A sharp test of that reading is a closure the firm did not choose. Since January 1, 2020, MACRA has barred the sale of Plans F and C to the newly Medicare-eligible, closing every such block to new 65-year-olds on a single statutory date regardless of the insurer's intent. This raises two questions. First, when a firm voluntarily closes an F or C block, does it reprice the retained pool the way it reprices any other deadpooled letter? Second, does the same repricing follow the *statutory* closure of blocks the firm would otherwise have kept open—or is it tied specifically to the firm's own decision to wind a block down?

On the first, a voluntarily closed F/C block looks similar to other deadpooled letters when each is placed on its own closure clock. The rest of this section takes up the second. We use Callaway–Sant'Anna event studies on each block's *own* closure clock: Event time is measured relative to the year a block closed to new entrants. For a block the firm closed voluntarily, that is its own filed closure year. For a block MACRA forced shut, it is 2020, the single statutory date on which every remaining F/C block stopped accepting new 65-year-olds. In both cases the control group is never-closing, never-deadpooling blocks of other letters, and each ATT is measured relative to event time -1. We report the contrast pooled across regulatory regimes here.[13]

Splitting F/C blocks by *how* they closed makes the point. Figure 5 runs the contrast on the CSG quoted-price index: a fixed basket of ages, weighted by the MCBS age distribution of Medigap holders and carried past the end of a block's quotes by the closed-block increases its carrier filed. Because the basket holds the age mix fixed, neither the pool aging nor the healthy leaving can move it; what it measures is the price the carrier set. F/C blocks the firm voluntarily closed before the ban, placed on their own closure clock, see their quoted price rise by \$229 five years after closure (95% CI $-$\$9 to \$468); F/C blocks left open until MACRA forced them shut, on the 2020 clock, rise by \$84 ($-$\$47 to \$214). The two quoted-price paths diverge, but neither five-year estimate excludes zero at the 5% level. Profit per enrollee separates them clearly (Figure 6): it rises by \$373 (\$183 to \$564) for blocks the firm closed, against \$92 ($-$\$30 to \$214) for blocks the statute closed, whose profit moves once in 2020, with the pandemic, and does not climb. The same plan letters, held under the same rules, are repriced when the firm chose to close them and not when the statute did. **A captive, aging pool is therefore not sufficient for the post-closure premium increase: the increase is a deliberate firm action, tied to the decision to wind a block down.** This complements Appendix G, where the timing of closure is shown to be a subsidiary-wide corporate decision exogenous to any single block's pool.

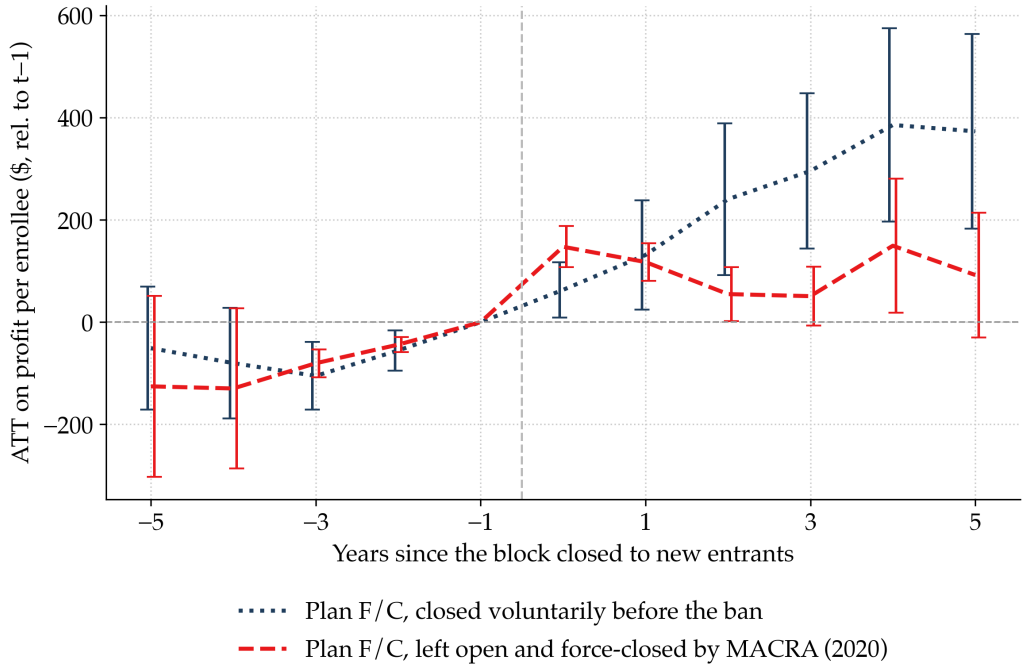

13. One feature of the comparison deserves note, because it is specific to the statutory arm. Every force-closed block has event time zero in 2020, whereas the voluntarily closed blocks are spread across the panel, so the forced arm's entire post-period coincides with the pandemic and its aftermath—a period in which utilization fell and insurer profits rose temporarily in every regulatory regime (Section 8.2). The design absorbs a shock common to all blocks, since the never-closing control blocks are observed in the same calendar years, so the concern is not a level effect of the pandemic but a differential one: Plans F and C are the most comprehensive letters and are held by the oldest enrollees, so their utilization may have moved differently from that of the control letters. We have not yet separated the two, and the forced-closure null should be read as provisional on that point.

Figure 5. Choice Versus Statute on a Quoted Price, Holding the Pool Fixed

Notes: Plan F/C blocks only. Outcome: the CSG quoted-price index, a fixed (Laspeyres) basket over ages 65–85 weighted by the MCBS age distribution of Medigap holders, annual 2025 dollars, extended past the end of a closed block's quotes by the closed-block rate increases its carrier filed. Callaway–Sant'Anna ATT by event time, pooled across regulatory regimes, doubly robust (`drimp`) with state controls. Navy dotted: blocks closed voluntarily before the 2020 ban, on their own closure clock. Red dashed: blocks force-closed by MACRA, on the 2020 clock. Control group: never-closing, never-deadpooling blocks of other plan letters (plan-letter controls not identified), restricted to block-years quoted in their own right. Universal base period (`long2`), $t-1$ normalized to zero. Enrollment-weighted. Standard errors clustered by NAIC company; bars are 95% confidence intervals. Joint pre-trend tests (leads $t-6$ to $t-2$): voluntary $p = 0.085$, forced $p = 0.002$.

Figure 6. Choice Versus Statute: Profit per Enrollee

Notes: Plan F/C blocks only. Callaway–Sant'Anna ATT on profit per enrollee (premiums minus claims, 2025 dollars) by event time, pooled across regulatory regimes, doubly robust (`drimp`) with state controls. Navy dotted: blocks closed voluntarily before the 2020 ban, on their own closure clock. Red dashed: blocks left open until MACRA force-closed them, on the 2020 clock. Control group: never-closing, never-deadpooling blocks of other plan letters; because no control block is an F or C, plan-letter controls are not identified. Universal base period (`long2`), $t-1$ normalized to zero. Enrollment-weighted. Standard errors clustered by NAIC company; bars are 95% confidence intervals. Joint pre-trend tests (leads $t-6$ to $t-2$): voluntary $p = 0.034$, forced $p = 0.000$.

7 Quantifying the Cost to Consumers

In the previous section, we established an estimate of firm profit from deadpooling. To quantify the total change in consumer surplus resulting from this practice, we must quantify transfers from people who remain in deadpooling plans, switching costs from people who are able to change to other risk pools, and deadweight loss from people who are not able to be apprived elsewhere and are priced out of the Medigap market. The sum of these three lost aspects of consumer surplus forms our estimate of the total cost of deadpooling.

7.1 Deadpooling Increases Premiums Unexpectedly

Table 2 reports Callaway-Sant'Anna (2021) (CS) difference-in-differences estimates of the average treatment effect on the treated (ATT) of deadpooling plan closure. Our controls group is the set of never-closed plans. Each panel shows the impact of deadpooling closure on a different outcome. Column 1 uses no additional covariates, Column 2 adds state fixed effects, and Column 3 adds state and plan-type fixed effects. The final column reports the enrollment-weighted mean of the outcome before closure, against which the estimates can be read. Alternate specifications and sample restrictions are reported in Appendix P.

The disjoint set of closing plans whose parent does not reopen is estimated on the same specification and reported beside them in Appendix P.2, so the two arms can be compared directly. The CS estimates show that paid premiums are substantially higher after plan closure. In the average enrollee's plan, inflation-adjusted annual premiums increased by $329 after plan closure. This is a 12.0% increase in prices compared to the $2,746 these plans charged before closing. Importantly, this price increase does not correspond to any increase in covered benefits or plan generosity. Contextualized another way, this increase is 1.3% of the average retired worker's annual Social Security benefit of $24,894 (U.S. Social Security Administration 2026), which would almost entirely consume the average senior's cost of living adjustment (SSA 2025).

We therefore read the deadpooling column as follows. The loss ratio and per-enrollee profit are the outcomes that carry the causal claim for this arm, being the two whose identifying assumption is not rejected in any column of Table 2; of the two, the loss ratio is in addition the least vulnerable to the composition problems of Appendix B, being invariant to the age and size of the pool. The premium and claims ATTs for deadpooling closers ($1,005 and $606) are reported for completeness and are consistent in sign and rough magnitude with everything else in the paper, but a failed pre-trend test means they should be read as upper bounds on the deadpooling-specific effect rather than as clean causal estimates, because part of the measured jump may reflect a divergence already underway before closure. The profit ATT of $398 does not carry that caveat. Appendix P.4 shows the failure is a property of these blocks rather than of the estimator: it appears under both doubly-robust estimators and is not an artifact of the choice between them. The per-enrollee harm figure we quote in Section 9.3 does not come from this table at all—it is estimated from within-block growth rates via (14)–(16), which never invokes parallel trends.

Read with that caveat, the table remains the paper's central causal result. Premiums rise $329 per enrollee after closure (12.0% of the $2,746 charged beforehand) and $1,005 for deadpooling closures specifically, with no change in benefits. Claims account for part of that increase and profit for the remainder, $183 per enrollee among all closers and $398 among deadpoolers, so the repricing is not merely a pass-through of a sicker pool's costs. That deadpooling plans charge *less* than other eventual closers before closing ($2,347 against $2,746) is consistent with attracting enrollees at low advertised prices before repricing them.

Table 2. Premiums and Profits Rise After Closure, and by More for Deadpooling Plans

	(1)	(2)	(3)	Pre-Closure Means
Panel A: Per-Person Premiums (2025 $)				
NAIC	$1,116***	$1,049***	$1,005***	$2,347
	(242)	(236)	(235)	
NAIC, CSG sample	$640***	$588***	$630***	$2,203
	(93)	(87)	(125)	
CSG	$407***	$379***	$435***	$2,844
	(70)	(65)	(78)	
Panel B: Per-Person Claims (2025 $)				
NAIC	$724***	$676***	$606***	$1,821
	(139)	(146)	(139)	
NAIC, CSG sample	$472***	$442***	$391***	$1,723
	(72)	(74)	(85)	
Panel C: Per-Person Profits (2025 $)				
NAIC	$392***	$373***	$398***	$526
	(107)	(96)	(100)	
NAIC, CSG sample	$167***	$146***	$238***	$479
	(42)	(30)	(46)	
Panel D: Loss Ratio (claims / premiums)				
NAIC	-0.035*	-0.038**	-0.056***	0.795
	(0.019)	(0.015)	(0.018)	
NAIC, CSG sample	-0.003	-0.003	-0.040***	0.788
	(0.014)	(0.010)	(0.010)	
State controls		X	X	
Plan type controls			X	
N (plan-block-years, deadpooling only)	111,097	111,097	111,097	
Unique blocks	12,478	12,478	12,478	
Subsidiaries	291	291	291	
Parent companies	207	207	207	
N (plan-block-years, CSG sample)	16,928	16,928	16,928	
Unique blocks, CSG sample	2,593	2,593	2,593	
Subsidiaries, CSG sample	118	118	118	
Parent companies, CSG sample	86	86	86	

Notes: Panels report Callaway–Sant'Anna (2021) aggregated ATT of plan closure on each per-person outcome. Each panel reports deadpooling plans only. The parallel estimates for the disjoint set of closing plans whose parent does *not* reopen are in Appendix P.2, alongside these, so the two groups can be compared directly. All monetary units represent annual payments and are adjusted to 2025 dollars. Regressions are weighted by total lives. *N* counts plan-block-year observations in the estimation sample, not unique plans. Standard errors in parentheses are clustered at the NAIC insurer level. *NAIC* rows use every block-year in the NAIC filings. *NAIC, CSG sample* rows estimate the same outcome only on block-years for which a CSG quoted price also exists (2014 onward), with control block-years limited to blocks quoted in their own right that year; any gap between the two rows reflects the sample, not the measure. The *CSG* row is the CSG quoted-price index: a fixed basket of ages 65–85 weighted by the MCBS age distribution of Medigap holders, carried past a closed block's last quote by the closed-block rate increases its carrier filed with the state. Counts for the CSG sample are for deadpooling blocks only. All estimates in this table use the doubly-robust inverse-probability-tilting estimator (`drimp`) with a universal base period (`long2`); Appendix P.4 reports the same table under the alternative doubly-robust estimator (`dripw`). The joint pre-trend test for every panel and column is reported in Appendix P.1, together with what it implies for how each panel should be read. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$. Joint pre-trend tests (leads $t-6$ to $t-2$, $t-1$ the base period; Appendix P.1): tests reject at the 5% level for premiums ($p = 0.000, 0.001, 0.004$ in Columns 1–3) and claims ($p = 0.000, 0.006, 0.025$); all other pre-trend tests in this table are not significant at the 5% level (profit $p = 0.263, 0.327, 0.188$; loss ratio $p = 0.362, 0.448, 0.260$).

In the first row of Panel A, we restrict to plans that deadpool, as subsidiary entry is consistent with strategic behavior. Premium increases are larger for deadpooling plan closures than for closures whose parent does not reopen ($1,005 against $329 in Column 3) and are at least $1,005 across all specifications. Deadpooling firms increase premiums by an average of 42.8% in the years after closure for a senior to maintain coverage. Prior to closure, deadpooling plans charge lower premiums than other plans that eventually close, potentially allowing firms to attract enrollees through lower advertised prices before initiating premium increases.

We next assess whether these larger premium increases are driven by rising claims or translate into higher insurer profits. Panel B reports the same Callaway-Sant'Anna specifications, but with average claims paid by the insurer as the outcome. It shows that deadpooling plans have lower average claims before closure, but substantially higher average claims after closure. This is consistent with low-cost beneficiaries leaving deadpooling plans in larger numbers and accelerating the concentration of high-risk individuals. Although claims increase after closure, that accounts for only part of the increase in premiums. In Column 3, higher claims absorb 60% of the deadpooling premium increase ($606 per enrollee); the remainder is insurer profit. That profit has two parts: $156 (16%) is the insurer's ordinary margin on the larger claims of a sicker pool, and $243 (24%) is a widening of the markup itself, the part that the loss-ratio estimates below isolate from any change in the pool's composition. From Column 3 of Panel C, we see that insurers profit an extra $183 per year and beneficiary after plan closure; this is $398 for plans that deadpool. Though plans cover fewer seniors after closure, each beneficiary who remains in the plan is 31.3% more profitable than before, and 75.8% more profitable in plans that deadpool. A natural alternative reading of the premium result is mechanical: enrollees who stay simply age onto higher rungs of an attained-age rate schedule. The CSG quoted-price results of Section 7.1 set that reading aside, because they price a fixed basket of ages that aging cannot move. We cannot rule out that aging and the selective exit of healthy enrollees also contribute, and we return to this in the loss-ratio results below.

To quantify the total magnitude of these payments, we aggregate the per-enrollee effect over the enrollees who actually bear it. For each calendar year we take the Callaway-Sant'Anna group-time estimates of the profit effect (estimated under the same state and plan-type adjustment as Column 3 of Table 2, whose pre-trend test the deadpooling arm does not pass, so this aggregate inherits that caveat and is best read as an upper bound) aggregate them across cohorts to obtain that year's average excess profit per enrollee, and multiply by enrollment in deadpooled blocks that have already closed in that year. Summing over the panel puts the cumulative transfer from seniors to deadpooling insurer profits at $5.7 billion, or $298.6 million per year on average. The same construction applied to premiums rather than profits (the full out-of-pocket burden on seniors, part of which funds the higher claims of a sicker pool rather than accruing to the insurer) gives $763.4 million per year, or $14.5 billion over the panel.

The same before-and-after-closure comparison under a conventional two-way fixed-effects specification, progressively adding year, state, plan-type, and plan fixed effects, yields similar results (Appendix P.7).

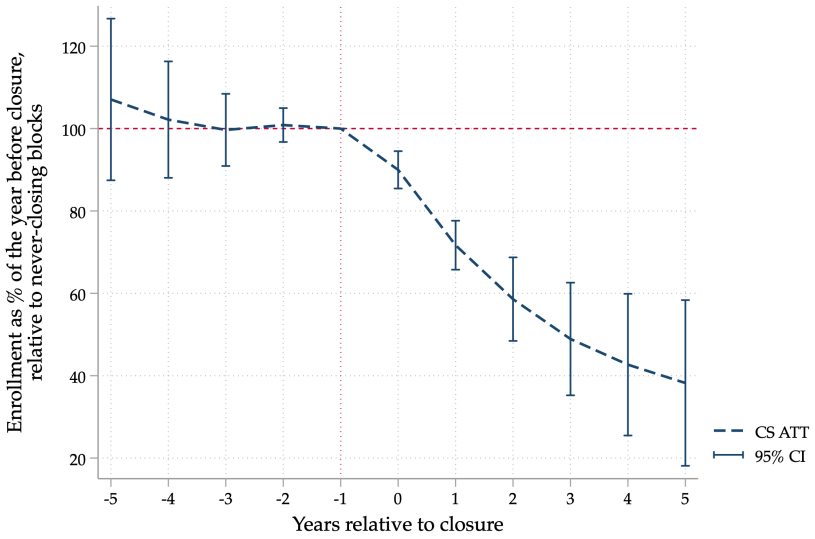

Why would beneficiaries remain in closed plans? In most states, seniors who have developed medical

conditions or are of advanced age are likely to be denied during medical underwriting, leaving them unable to switch their plan without losing the comprehensive coverage offered by Medigaps. The concentration of higher-risk beneficiaries in closed plans is consistent with the rise in claims after plan closure. Other beneficiaries may remain enrolled due to inattention.

The size of a premium increase during closure is positively related to the magnitude of the fall in coverage. Each additional $100 of first-year premium increase is associated with 1.2 percentage points more disenrollment, and a block whose premium rises ten percentage points faster than another loses roughly an additional 2.7 percentage points of its enrollment in the first year (Appendix Q). Disenrollment shows a much larger reaction to the change in what enrollees pay than to the markup level, which is consistent with a world in which people leave plans in response to changes in price. Available data does not allow us to directly observe whether seniors switch to another Medigap plan, forgo supplemental coverage, switch to Medicare Advantage, or leave the Medicare program altogether.

To directly confirm that people leave these plans at closure, the enrollment event study in panel D of Figure 3 shows covered lives falling steadily after closure with no pre-trend. Figure 7 expresses a closing block's enrollment as a percent of its enrollment the year before closure, relative to never-closing blocks, using the same Callaway–Sant'Anna design as the closure results (doubly robust, universal base year, state and plan-type covariates, weighted by year-before-closure enrollment, clustered by NAIC company; 10,884 closing blocks, 6,886 controls). A closing block keeps 48.9% of its enrollees three years after closure (95% CI 35.2%–62.6%) and 38.2% five years after (18.1%–58.3%), with no pre-trend ($p = 0.646$). The NAIC filings have no zero-enrollment rows, so a block that empties drops out of the panel, and retention among blocks still reporting overstates true retention.

Figure 7. Enrollment After Closure, as a Percent of the Year Before

Notes: 100 plus the Callaway–Sant'Anna ATT on enrollment normalized by year-before-closure enrollment; never-closing controls normalized by their own mean enrollment. 95% confidence intervals.

The following figures present Callaway-Sant'Anna (2021) event study estimates of the effect of plan closure on per-person premiums, claims, profits, enrollment, and loss ratios. These figures use

never-closed plans as the control group and are adjusted for state and plan-type differences via doubly-robust regression. All series are normalized to event time -1, so each point shows the treatment effect relative to the year before closure. Pre-period trends are flat for non-deadpooling closers and for the loss ratio in both arms, but not for the dollar outcomes among deadpooling closers, where the formal test in Table 2 rejects; the pre-period points in those panels should be inspected rather than assumed flat. Premiums, claims, and profits all rise after closure, while enrollment falls steadily. The loss ratio also falls post-closure, confirming that premium increases outpace claims growth in percentage terms.

Pre-closure trends are flat for profit, the loss ratio and enrollment, but the joint pre-trend test rejects for premiums ($p = 0.016$) and claims ($p = 0.042$). Average paid premiums (Panel C, navy) climb steadily after closure, exceeding $600 per enrollee by three years out (roughly a 26% increase) with no corresponding change in the benefits covered. Claims (Panel C, maroon) also rise, consistent with a pool that ages and sickens as healthy members leave, but they account for only about two-thirds of the premium increase; the residual third is per-enrollee profit (Panel A), which rises by roughly $300 (nearly $460 for deadpooling plans). The loss ratio (Panel B) (claims divided by premiums) therefore *falls*: because an older pool raises claims and premiums together, a declining ratio cannot be produced by aging alone and is the composition-robust statement that premiums rise faster than the costs they cover. Enrollment (Panel D) drains away over the same window, so the repricing coincides with a steady loss of members rather than a stable captive pool; those who remain are disproportionately the ones who cannot pass underwriting to leave.

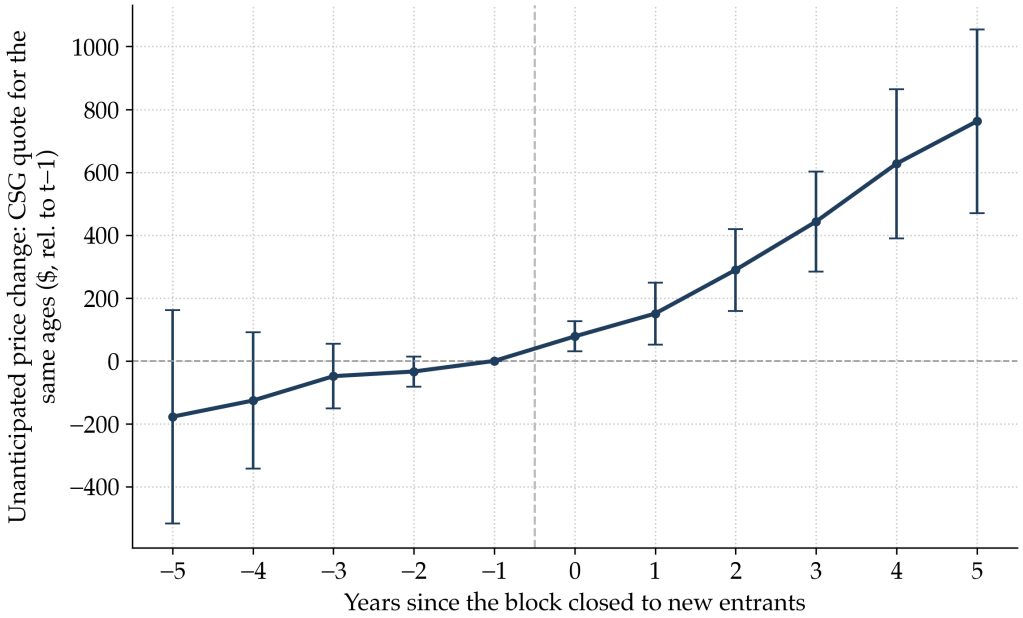

The five-year effects plotted here are larger than the aggregated ATT reported in Table 2, although both come from the same estimator, the same sample and the same specification. The difference is the aggregation. The table reports the Callaway–Sant'Anna *simple* aggregate, a single number that averages every post-closure event time together; this figure reports the ATT separately at each event time. Because closure sets off a ramp rather than a jump (premiums climb year by year as the pool ages and the healthy leave) an average taken over the whole post-closure window necessarily lies below the value five years out. The two are consistent summaries of the same estimates: the table answers what closure does on average over the years we observe, the figure answers what it has done by a given year.

Figure 3 measures the premium a closed block collects per enrollee, which moves with who is left in the pool as well as with what the carrier charges. Figure 8 removes the first of these. It is the closure effect on a *quoted* price index (a fixed basket of ages 65 to 85, weighted by the MCBS age distribution of Medigap holders, so the pool is held constant by construction) extended past the point where a closed block leaves the quoting feed by the closed-block rate increases its carrier filed with the state. Because the ages are held fixed, nothing in this series comes from an enrollee moving along the rate schedule they bought: it is the unanticipated increase.

An enrollee who reads their block's rate schedule already knows that premiums climb with age, so part of the increase in Figure 8 is something they could see coming. Table 3 separates the part they could from the part they could not. For an enrollee aged a in the year before closure, the schedule in that year already states what someone aged $a + 5$ pays; the difference between that and their own current premium is the increase the age gradient alone implies. What the schedule cannot tell them is that the schedule itself will move. The two pieces sum to the total increase by construction, so nothing is left in a residual.

Across all entry ages the deadpooled enrollee pays $1,103 more after five years, of which $351 was visible in the schedule they bought into and $752 was not. In a block that never closes the same enrollee pays $434 more, of which $124 is unanticipated. The gap between those two unanticipated figures, $628,

Figure 8. The Closure Effect on a Quoted Price, Holding the Pool Fixed

Notes: Callaway–Sant'Anna ATT of plan closure by years since closure, normalized to zero at $t = -1$, with the estimator, covariates, clustering and weighting of Figure 3: never-closing plans as the control group, doubly robust (`drimp`) with state and plan-letter controls, universal base period (`long2`), enrollment-weighted, standard errors clustered by NAIC company; bars are 95% confidence intervals. Outcome: the CSG quoted-price index, a fixed (Laspeyres) basket of ages 65–85 weighted by the MCBS age distribution of Medigap holders, in annual 2025 dollars, carried past the end of a closed block's quotes by the closed-block rate increases the carrier filed.

Table 3. Most Increases in Premiums Are Not Foreseen

	Baseline premium	Total increase	Anticipated (age gradient)	Unanticipated (repricing)
Deadpooled blocks				
Aged 65 at closure	\$2,238	\$897	\$305	\$592
Aged 70 at closure	\$2,543	\$1,072	\$376	\$696
Aged 75 at closure	\$2,919	\$1,142	\$347	\$796
Aged 80 at closure	\$3,266	\$1,178	\$313	\$865
Never-closing blocks				
Aged 65 at closure	\$2,447	\$776	\$782	\$-6
Aged 70 at closure	\$3,229	\$319	\$267	\$52
Aged 75 at closure	\$3,496	\$347	\$184	\$163
Aged 80 at closure	\$3,680	\$329	\$115	\$214
All deadpooled	\$2,711	\$1,103	\$351	**\$752**
All never-closing	\$3,229	\$434	\$310	**\$124**

Notes: One never-closing UnitedHealthcare Plan A market in Oklahoma, whose quote for a 65-year-old rose about sixfold in five years, is dropped as an outlier. Annual premiums in January 2025 dollars, lives-weighted by each block's enrollment in the year before closure. For an enrollee aged a in that year, with b the year before closure: the total increase is $p(a+5,\, b+5) - p(a,\, b)$; the anticipated part is $p(a+5,\, b) - p(a,\, b)$, what the baseline schedule already showed a person five years older paying; and the unanticipated part is $p(a+5,\, b+5) - p(a+5,\, b)$, the schedule itself moving. The three are an exact identity. Prices are CSG quoted rates for a non-smoking applicant, carried past the end of a closed block's quotes by the closed-block rate increases the carrier filed with the state; all are the female quote, which is the gender the CSG age profile is built on. Never-closing blocks are measured over the same calendar years, so the deadpooling-specific surprise is the difference between the two unanticipated columns, \$628 per year, not the deadpooled figure itself. A block enters only if CSG quotes it at the enrollee's age in the baseline year *and* at the age they reach five years later, which restricts the sample to closures between 2015 and 2020: 637 of 5,248 deadpooling blocks, but 31.7% of deadpooled enrollment, since the blocks CSG quotes at both endpoints are the larger ones.

is what closure adds to the part of the bill nobody could have planned for, and it is remarkably stable across entry ages—between $586 and $667 from age 65 to age 80, with no trend. The anticipated component, by contrast, is almost identical in the two groups. Both sets of enrollees could read roughly the same age gradient; they differed in what happened to the schedule underneath it.

7.2 Calculating Lost Consumer Surplus: Transfers and DWL

The estimates in Section 7.1 are causal but local: they say what a deadpooled block does to one enrollee in one year. This subsection asks how much harm deadpooling does in total, and we take three approaches. The first asks how profits would be reduced if an existing regulatory standard were applied, the second what a randomly chosen trapped enrollee expects to lose, and the third how much of that loss is a transfer and how much is surplus destroyed outright.

Start with the regulatory benchmark. Medigap insurers in the individual market must spend at least 0.65 of premiums on claims; Medicare Advantage plans must spend 0.85. For a block collecting premiums P and paying claims C, a loss-ratio floor f obliges a rebate of

$$R(f) \;=\; \max\{0,\; f \cdot P - C\}\,, \tag{9}$$

which is zero if the insurer spends f or more of collected premiums on medical claims, and positive if it spends less. Deadpooled closed blocks run a loss ratio of 0.768, against 0.802 in open blocks. The Medigap floor is therefore slack: enforced as a rebate it would return only $31 per enrollee per year. Held instead to the standard that already applies elsewhere in Medicare, a deadpooled block would owe $350 per enrollee per year, against $201 for an open block, and $5.7 billion across the panel. Read the other way round, if Medigap were held to the profit standard that already applies elsewhere in Medicare, that figure is what consumers overpaid.[14]

These figures are mechanical accounting quantities (premiums collected, claims paid, one statutory ratio) with no control group, no parallel-trends assumption, and no estimation. Yet they land close to the causal estimates. The aggregate rebate of $5.4 billion at the administered unit ($5.7 billion at the block) sits within a few percent of the $5.7 billion that the year-by-year difference-in-differences aggregation produces; per enrollee, the $331 rebate is about a sixth below the causal profit ATT of $398 in Panel C of Table 2. Two methods sharing no identifying assumption agree on the aggregate to within a few percent, and on the per-enrollee magnitude to within about a sixth. Each rests on a small but different set of assumptions (the difference-in-differences estimate is enrollment-weighted and divides by a headcount, the rebate calculation does neither) so landing in the same ballpark is the reassurance, not the precision.

The second approach prices the harm *ex ante*: it asks what a senior should expect to lose on the day their block closes, before knowing how long they will stay. That is the relevant number for someone deciding

14. The unit at which the shortfall is computed matters, because a block already above the floor owes nothing and cannot offset one below it. Our block (insurer × state × plan letter × market) is finer than the insurer × state × market cell at which rebates are actually administered, so the block-level sum is an upper bound. Aggregating instead to insurer × state × year gives $331 per enrollee and $5.4 billion; pooling the entire deadpooled book, so that every block offsets every other, gives $266 per enrollee and $4.3 billion. We report the administered unit as the central figure and the other two as bounds.

whether to buy into a block, and it is smaller than the ten-year figure because most enrollees die or leave before ten years are up. The $6,113 ten-year figure in Section 9.3 is the excess premium paid by a senior who stays enrolled for the full ten years. Most do not: enrollment-weighted retention in a deadpooled block is 0.29 at five years and 0.16 at ten. Writing Δ_s for the excess premium a trapped enrollee pays in year s after closure and S_s for the share of the original block still enrolled then, the expected burden over a horizon H is

$$\mathbb{E}\big[\text{excess premium}\big] \;=\; \sum_{s=1}^{H} S_s \cdot \Delta_s, \tag{10}$$

which weights each future year by observed retention rather than conditioning on survival to the horizon. This gives the excess premium expected by a randomly chosen enrollee on the day their block closes: $803 over five years and $1,977 over ten. Aggregated over the 1,235,226 enrollees trapped in 2020, one year's closures impose $2.4 billion of excess premiums over the following decade.

The gap between $1,977 and $6,113 is not a discrepancy but a selection effect, and it points at the harm the premium figures cannot see. Enrollees leave the expectation by dying or by dropping the plan, and only the first is benign.

The third approach separates the two economically distinct pieces. Excess premiums paid by a senior who stays are a transfer: the senior is poorer, the insurer richer, and no surplus is destroyed. A senior who gives up coverage because the premium outran their willingness to pay is a different matter. They forgo the risk protection a Medigap provides, and the insurer collects nothing from them. That loss is not a transfer to anyone.

Five years after closure, mortality alone—at the 4.3% annual hazard of a typical Medigap pool[15]—would leave 0.80 of the original block alive and enrolled. Observed retention is 0.29. The 51.1% gap is disenrollment beyond what death explains: 630,760 people for the 2020 cohort alone.

These leavers are not harmed in the same way, so we split them by whether they can obtain another Medigap. Using the MCBS underwriting exercise of Appendix E, 26.8% of current Medigap enrollees would pass medical underwriting in every market and could therefore switch to another Medigap, while 73.2% would be rejected in most markets and cannot.[16] Writing N for the leavers beyond what mortality explains, ρ for the share who would be rejected, v for the annual surplus an out-of-market beneficiary forgoes and κ for the cost of switching, the destroyed surplus is

$$\text{DWL} \;=\; \underbrace{\rho\, N\, v}_{\text{lose coverage}} \;+\; \underbrace{(1-\rho)\, N\, \kappa}_{\text{switch, at a cost}}, \tag{11}$$

15. We compute this rate rather than assume it. The MCBS (Fall 2017–2023, Medigap enrollees, survey-weighted) gives the age composition of the Medigap population, and the Social Security period life table (Social Security Administration 2024) gives the annual probability of death for ages 65–74, 75–84 and 85 and over (men and women pooled, weighted by the number alive at each age); their weighted average is 4.3%. The same rate is used for every mortality adjustment in the paper. It enters the harm accounting only through the counterfactual: who stays and pays is observed retention, and mortality decides how many of those who left would have died anyway. It also weights future years in the per-person present values below. A closed block's pool is older and sicker than the average Medigap pool, so its true mortality is probably higher; a higher rate would attribute more departures to death, lowering the number priced out and the deadweight loss, and would shorten the expected stay behind each present value.

16. The distribution is close to bimodal (73.2% of enrollees are rejected in more than half of the 2022 markets and almost none sit in between) so this split is insensitive to whether "can switch" requires acceptance everywhere or merely somewhere.

so that total harm is this plus the transfer paid by those who stay. The 73.2% who cannot switch lose comprehensive coverage entirely; we value their loss at the consumer surplus a marginal out-of-market enrollee forgoes, $1,350 per year from the structural model, for $623.1 million.[17] The 26.8% who can switch keep coverage, so their loss is only the cost of switching (underwriting paperwork, physician exams, and agent search) which we value at the $30 median Medigap search cost of Lin and Wildenbeest (2020), for $5.1 million. The destroyed surplus is thus $628.2 million, against a transfer of $491.6 million on the same cohort. Total harm is $1119.8 million, so **each dollar of deadpooling profit costs seniors $2.28**. Deadpooling is not merely redistributive: a substantial part of the harm it does is surplus that no one captures.

The destroyed-surplus figure above imputes a dollar loss to each leaver. We can instead read that loss off the enrollees' own behavior, with no imputed valuation at all. As a closed block's premium ramps up, an enrollee quits when the price passes their willingness to pay, so someone still enrolled one year but gone the next reveals a consumer surplus (a willingness to pay above the competitive premium) between the two years' cumulative premium increases. Adding up, year by year, how many people left and how much surplus each of them gave up traces out a demand curve, and the area under it is the surplus the ramp destroys. Figure 9 plots the implied curve: consumer surplus above the competitive premium against the cumulative share of the closing cohort priced out. Charging only the premium increase in excess of what open blocks levy, and valuing each leaver at their own revealed surplus, the destroyed surplus for the 2020 deadpooled cohort is $202.4 million per year ($135.3–$269.6 million across the surplus band). That this revealed-preference number lands beside the $628.2 million we obtained by imputing an out-of-market surplus to the same leavers (two calculations that share no valuation assumption) is a second piece of evidence that the loss is real.[18] Carrying the observed surplus through the harm accounting in place of the imputed one, not only alongside it, the destroyed surplus is $202.4 million, total harm is $694.1 million, and each dollar of deadpooling profit costs seniors $1.41) lower than the $2.28 the imputed valuation gives, and resting on no valuation assumption of ours at all. Per leaver the two differ more than fourfold ($231 against $1,350), which is what one should expect: the revealed figure prices the *marginal* leaver, who is close to indifferent by construction, while the imputed figure prices the average out-of-market beneficiary.

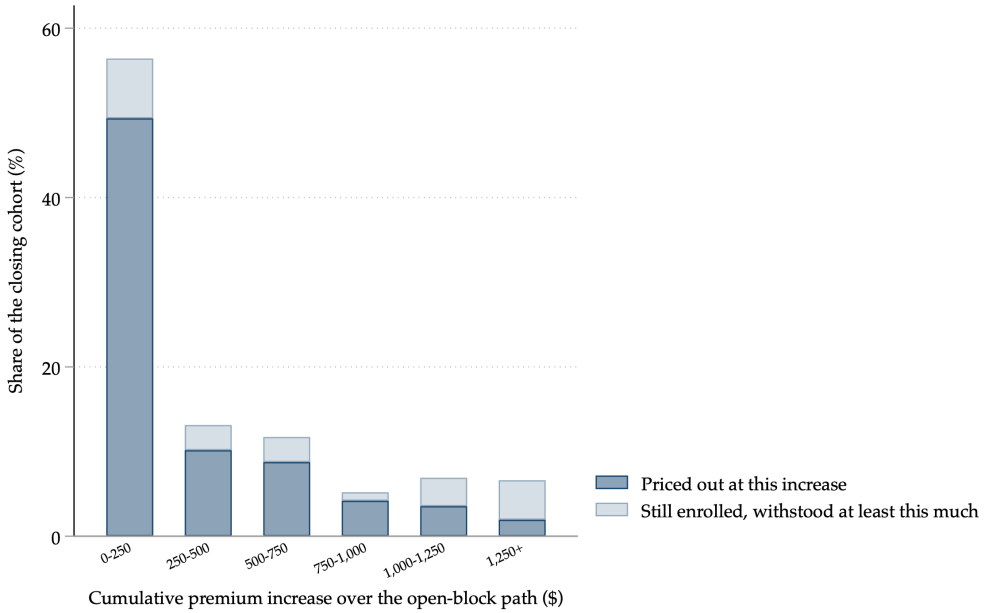

The estimates above price one margin at a time. Assembling them into a single accounting of what happens to a block's enrollees is worth the effort, because the loss takes three different forms and only one of them is the premium ramp.

We follow the cohort enrolled at closure through time rather than sorting people into fixed groups,

17. This figure is a claims-based certainty equivalent, not an estimated demand parameter: in the structural model of Section 9.3 each enrollee's willingness to pay for coverage is the expected present value of their claims over the remaining horizon plus a CARA risk premium, and $1,350 is the mean of $\max(0,$ willingness to pay $-$ cheapest available premium$)$ over out-of-market beneficiaries in the baseline. It is therefore constructed from the claims and health-transition data rather than inverted from market shares. The revealed-preference estimate below provides an independent, demand-side check on it.

18. Extending the same construction to *all* closing plans, not only those that deadpool, gives $140.2 million: non-deadpooling closures price out a far smaller share of their cohort, which is the selection that defines deadpooling. The wider sample yields the *smaller* total because the construction nets each leaver's surplus against the excess premium they were charged, and non-deadpooling closers contribute close to nothing on that margin (per leaver the figure falls from $231 to $85 even as the cohort roughly triples.

Figure 9. Three Quarters of a Deadpooled Cohort Are Priced Out; Those Who Remain Absorbed the Largest Increases

Notes: The distribution of a deadpooled block's closing cohort across the size of the premium increase they faced. Binning is at the *block* level: for each of 747 blocks that closed early enough for seven post-closure years to be observable, we take that block's own premium path net of ordinary open-block growth and its own retention path, so the increase on the horizontal axis is the one that block's enrollees actually faced rather than a fitted average. The window is a calendar requirement, not a survival one—a block whose enrollees have all gone by year four contributes those departures rather than being dropped for having no later rows, since emptying out is the strongest form of being priced out and excluding it would keep only blocks that retain people. The two segments of each bar are different objects and are not interchangeable. The dark segment is the share of the cohort *priced out at* an increase in that $250 range, measured at the increase in force when they left. The light segment is the share *still enrolled* at seven years whose block never imposed more than that range, so it records the largest increase they are known to have absorbed without leaving: their reservation threshold is right-censored and this is a lower bound on it, not the threshold itself. Placing them this way is what distinguishes an enrollee who held on through a large increase from one who was never asked to absorb anything, which a single unlabelled residual bar cannot do. Of the 22.1% still enrolled, 21.2% sat in blocks that did pass $1,250, but 59.0% were in blocks that never passed $750 and 32.1% in blocks that never passed $250. Departures are measured net within each block-year, so the two segments sum to exactly 100% of the cohort: 77.9% priced out within the window and 22.1% still enrolled at the end of it. Premiums are winsorized at 1/99 and mortality is not netted out. The price on the horizontal axis is the CSG quoted-price index rather than the realized per-enrollee premium, weighted over ages 65–85 by the MCBS age distribution of Medigap holders and carried past the end of a block's quotes by the closed-block rate increases its carrier filed. That choice matters for this figure in particular: under attained-age rating part of a realized premium increase is the enrollee climbing the rate schedule rather than the block repricing, which would put people in a higher willingness-to-pay band than they belong in, whereas a fixed basket holds the age mix constant by construction. The open-block path the increase is measured against is estimated on the same index among never-closing blocks, so a fixed-basket treated path is not being compared with a composition-moving control. Repeated for all closing plans, the exercise shows that deadpooled closers price out 77.9% of their cohort against 65.0% for ordinary ones, and carry substantially more of their mass in the largest increase bin. Integrating the exit margin values the surplus destroyed at $202.4 million per year, arrived at with no imputed valuation and landing beside the $628.2 million the imputation approach gives.

because enrollees do not stay in one group: someone leaves after a year, someone else after four, and each bears the excess premium only while enrolled. In each year, those still on the block pay that year's excess premium, aging-netted as in Appendix B. Those who leave divide by whether they can pass medical underwriting elsewhere: 23.6% of leavers can re-buy Medigap and pay a one-time switching cost, while 76.4% cannot and bear an out-of-market loss for every remaining year. Over ten years this leaves 16.0% of the original *deadpooled-block* cohort—the enrollees on that block on the day it closed, not Medigap enrollees generally—still enrolled, 19.8% having switched, and 64.2% out of the Medigap market. Switchers bear a search cost, which Lin and Wildenbeest (2020) estimate at a median of $30 in this market. Because switching also requires an application and medical underwriting, we treat that as a lower bound; the total is insensitive to it either way, since switchers are the smallest group.

Those who cannot re-buy lose the coverage itself. We value that loss from the agent survey, which asks brokers to price the attributes a client gives up—no network restrictions, no prior authorization, no claims hassles, predictable out-of-pocket costs—*net of* the dental, vision, and hearing benefits gained in Medicare Advantage. The median agent values that bundle at $270 a month, or $3,240 a year. Because the valuation is already constructed as a Medigap-versus-Advantage comparison, it prices the enrollee who moves to Advantage rather than one who goes without coverage entirely, which is the relevant margin here. From it we net the premium the enrollee no longer pays, at the open-block level of $2,603 rather than the deadpooled path. We hold that premium fixed rather than growing it, for two reasons—it is an enrollment-weighted average across ages and across the twenty closure years in the panel, so it already embeds the market's age mix, and in 2025 dollars it is close to flat from 2010 onward.

Table 4 collects the result: $2,712 per enrollee over ten years, of which the premium ramp borne by those still enrolled is the larger share and the out-of-market loss most of the rest, switching costs being negligible at $4. Per person the two harmed groups are far apart—$9,951 for someone still enrolled at ten years against $1,739 for someone pushed out—but only 16.0% of the cohort is still enrolled against 64.2% out of the market, so the two channels end up of comparable size in the total. On the realized NAIC premium the total is similar ($2,341 against $2,712), but more of it is deadweight loss (77% against 41%), because the realized ramp is shallower and the open-block premium a leaver avoids is lower.

This is a reduction in *consumer* surplus, and the distinction matters. The excess premium is a transfer: the enrollee is poorer, no surplus is destroyed, and the money goes partly to the insurer's margin and partly to the higher claims of the pool left behind. Only the first part is a transfer *to the insurer*. The out-of-market loss is not a transfer to anyone on the consumer side, but neither is it obviously destroyed on the producer side, because an enrollee who leaves Medigap for Advantage is typically still insured, often by the same parent. What the table measures is therefore what enrollees lose, not what society loses; the two coincide only for the search costs. That the market-exit channel dominates is the substantive point, and it is invisible to the per-enrollee estimates of Section 7.1, which by construction follow only the people who stay.

The demand curve also delivers a distribution of valuations, plotted in Figure 9. Consumer surplus over the competitive premium follows a Weibull law with median $276 per year and a heavy right tail: 16.3%

Table 4. Reduction in Consumer Surplus for the Enrollees of a Deadpooled Block

Panel A: Cost per enrollee of a deadpooled block, present value at closure

	Cost per person in group (share of cohort)			
Horizon	Repriced	Switching	Out-of-market (DWL)	Cohort average
One year	\$136 (78.1%)	\$27 (5.2%)	\$361 (16.8%)	\$168
Five years	\$2,715 (29.0%)	\$24 (16.8%)	\$1,003 (54.2%)	\$1,336
Ten years	\$9,951 (16.0%)	\$22 (19.8%)	\$1,739 (64.2%)	**\$2,712**

Panel B: All deadpooling closures 2006–2020, first five years after closure (\$ millions)

	Markup	Switching	Out-of-market (DWL)	Total
Per year of closures	114.9	0.6	34.0	149.5
All 15 closure years	1,723	9.6	510	2,243

Notes: Present value per enrollee *at closure*—a cohort average over everyone on the block, not the amount any one person bears. Discounted at 5%, matching the firm-side valuation of Section 6.2 so the two sides of the same transaction are comparable, and weighted by survival at the 4.3% annual mortality hazard. The first three columns are the three forms the loss takes—excess premium paid while still enrolled, the one-time search cost for those who re-buy Medigap, and the out-of-market loss for those who cannot—each reported as the cost borne by a person *in that group*, with the share of the cohort in the group in parentheses. The three shares partition the cohort and sum to 100% within a row, so the cohort average in the fourth column is the share-weighted sum of the three, and is the figure comparable to the per-enrollee estimates elsewhere in the paper. The switching and out-of-market channels are deadweight loss; the repriced channel is a transfer out of the stayer's pocket, part insurer margin and part the higher claims of the sicker pool that remains (Section 7.1). At ten years 41% of the total is deadweight loss. Retention is observed at five and ten years; the one-year row uses the retention curve interpolated between closure and year five. The premium path is the CSG quoted price rather than the realized per-enrollee premium: the level at closure is the MCBS-weighted quoted rate a deadpooling block charges in the year before it shuts (\$2,844), and it then grows at 5.26 percentage points a year above the open-block path. That wedge is the difference between two *diagonals*—what one enrollee is charged as they age inside a closed block, against what they would have been charged aging inside an open one—each weighted by the MCBS age distribution of Medigap holders, so aging enters both sides and nets out without a separate adjustment. Panel B follows every deadpooling closure 2006–2020 (2,743,098 enrollees at closure) for five years in January 2025 dollars, undiscounted; its first column is only the markup widening of equation (13) (the premium rise beyond what the higher claims cost at the pre-closure loss ratio), so it is smaller than the repriced column of Panel A, which also counts the claims pass-through. Each dollar of markup costs enrollees \$1.30 in total.

of enrollees never leave over the horizon we observe, so their surplus exceeds the top of the ramp. This recovers the spread of valuations from market behavior rather than from an assumed parametric form.

Two robustness questions remain, and both are developed at length elsewhere. The first is whether the harm should be netted against a cheaper entry price. Every estimate above uses post-closure block-years only and is normalized to event time -1, so a block that begins cheap has that level absorbed into its own baseline. Deadpooled blocks do charge less while open (\$2,415 per enrollee against \$2,852 in never-closing blocks) so trapped enrollees might merely be repaying an earlier discount. They are not: a newly opened block holds younger, cheaper people, and per dollar of expected cost a deadpooled block charges *more* than a never-closing one even before it closes (1.311 against 1.235). Conditioning on state, plan letter and block age leaves no gap, and quoted rates show deadpoolers pricing above the market at every age (Section 7.5). We nonetheless report a floor that concedes the objection: treating the conditioned gap as a genuine discount over the block's open years reduces the ex-ante ten-year harm from \$1,977 to \$1,550, and conceding the entire unconditioned gap still leaves \$440.

The second question is the control group: deadpooling parents are large, so a never-treated group that pools small operators with them may not be the right comparison. Against a size-matched benchmark (the market's largest carrier, which runs one continuously-open block per market and never deadpools) deadpooled blocks earn \$105 more per enrollee per year, or \$1.7 billion across the panel; normalizing by claims to allow for the sicker pool gives \$1.8 billion. Appendix F.2 reports the comparison in full.

This benchmark is deliberately unfavorable to our argument, and the gap from the $5.7 billion headline is instructive rather than contradictory. The benchmark is itself a high-margin operator (its markup of 1.255 exceeds the 1.235 of never-closing blocks generally) so measuring deadpoolers against it asks how much more they extract than the most profitable firm that declines to deadpool, not how much more they extract than they themselves did before closing. The comparison is also a level difference rather than a difference-in-differences, and deadpooled blocks begin *below* the benchmark in per-enrollee profit and overtake it only after closure; a levels comparison silently forgives that starting deficit, while the event study in Table A5 does not, which is why its ATT of $457 per enrollee exceeds the $105 level gap. We therefore read $1.7 billion as a conservative floor on the transfer and $5.7 billion as the central estimate. Deadpoolers also out-mark the benchmark even while their blocks are open (1.311 against 1.255), which is difficult to reconcile with any account in which the closed-block rent compensates for cheap entry.

7.3 How Much of the Premium Rise Is Profit?

The transfer above counts the whole rise in per-enrollee profit after closure. Not all of that is extracted by the closure. Per stayer-year, the deadpooling premium rise in column 3 of Table 2, $\Delta P = \$1{,}005$, splits into three parts:

$$\Delta P \;=\; \underbrace{\Delta C}_{\text{higher claims}} \;+\; \underbrace{\Delta C\left(\frac{1}{LR_0}-1\right)}_{\text{normal margin on them}} \;+\; \underbrace{\left(\Delta P-\frac{\Delta C}{LR_0}\right)}_{\text{markup widening}}, \tag{12}$$

where $\Delta C = \$606$ is the rise in claims and $LR_0 = 0.795$ is the deadpooling blocks' loss ratio before closure. The first part, $606 (60% of the rise), pays for an older and sicker pool: enrollees pay it and no one profits from it. The second, $156 (16%), is the margin the insurer would have earned on those claims at its pre-closure loss ratio; an attained-age contract prices aging at the same loading, so this part is not extracted by closing the block. The third, $243 (24%), is pricing beyond what the higher claims justify at the old margin. We take only this third part as the transfer. The second and third together are the $398 profit rise. Multiplying the premium rise by one minus the year's average loss ratio would understate the claims share, because that average includes all the claims the block already paid: the marginal loss ratio on the rise is 0.60.

Summed over every deadpooling closure from 2006 to 2020 (15 cohorts and 2,743,098 enrollees at closure), each followed for five years,

$$\text{Transfer} \;=\; \sum_{g=2006}^{2020}\sum_{t=1}^{5}\left(\Delta P-\frac{\Delta C}{LR_0}\right)N_{g,t}, \tag{13}$$

where $N_{g,t}$ is the number of enrollees still in cohort g's closed blocks t years after closure, counted in the filings. People who leave or die stop paying, so no mortality adjustment enters. The 7,099,058 enrollee-years give a transfer of $1,723 million, or $114.9 million per year of closures.

Alternative ways of quantifying the transfer, including the loss-ratio event study ($1,673 million) and CSG quoted prices net of open-block growth ($1,563 million), give similar results and are reported in

Appendix C.

The rest of the harm accounting follows the cohorts the same way. Of the 2,743,098 enrollees at closure, 1,011,481 are still enrolled five years later and pay the markup throughout. Leavers beyond the 4.3% annual mortality divide by underwriting: 26.8% pass and switch, 321,621 people paying a one-time switching cost of $30 each, for $9.6 million; the other 877,187 leave Medigap and lose the plan's value, valued from when they left as in the revealed-preference construction above, for $510 million. Anyone who leaves before year five pays the markup while enrolled and is then counted as a switcher or leaver. Panel B of Table 4 adds these up. Total lost consumer surplus is $2,243 million ($2.24 billion), or $149.5 million per year of closures, so **each dollar of markup costs seniors $1.30**. Years after the fifth are not counted, so every figure here is a lower bound.

7.4 The burden on a trapped stayer

To gauge the harm from the enrollee's side, we translate the estimated premium ramp into the lifetime cost borne by a senior who keeps a deadpooled plan. Reading both growth rates off the panel, per-enrollee premiums in a deadpooled block rise about 7.7% per year after closure, against only 2.4% per year in never-closing (open) blocks—a gross wedge of 5.3% a year that compounds. Part of that wedge, however, is mechanical rather than harmful. A closed block issues no new policies, so its pool ages about a year every year, while an open block refreshes with new sixty-five-year-olds and holds its mean age roughly flat; under attained-age rating the closed block's pool-average premium therefore climbs even if the insurer never files a rate increase. A trapped stayer would have ridden that same age schedule in an open block, so this drift is not part of what deadpooling costs them. Appendix B nets it out using the CSG quoted-rate age gradient, which is identical for deadpoolers and non-deadpoolers—so a stayer faces the same age curve whether or not the block closes, and the netting is legitimate.

Both growth rates are estimated on the plan-block-year panel, each within its own sample. For deadpooling closers we fit the post-closure ramp over the first nine years since closure,

$$\ln P_{it} \;=\; \alpha_i \;+\; g_{\mathrm{dp}}\,(t - G_i) \;+\; \varepsilon_{it}, \qquad 0 \le t - G_i \le 8, \quad DP_i = 1, \tag{14}$$

and for the counterfactual we fit the secular trend in blocks that never close,

$$\ln P_{it} \;=\; \alpha_i \;+\; g_{\mathrm{cf}}\,(t - 2006) \;+\; \nu_{it}, \qquad G_i = \infty, \tag{15}$$

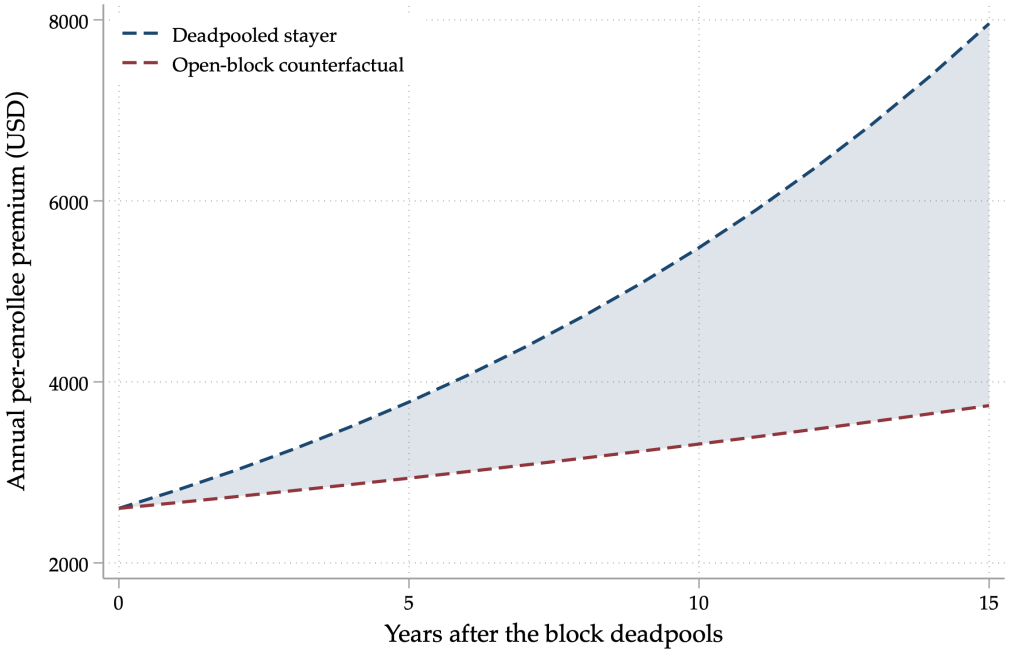

where P_{it} is the per-enrollee premium winsorized at the first and ninety-ninth percentiles, α_i is a block fixed effect, both regressions are weighted by covered lives, and standard errors are clustered at the parent-company level. Neither specification includes year fixed effects, so each slope is a *total* growth rate rather than a deviation from a common trend; this is what makes the difference $g_{\mathrm{dp}} - g_{\mathrm{cf}}$ the deadpooling-specific wedge rather than a residual.

Because the α_i absorb each block's premium level, identification comes entirely from within-block movement over time: (14) asks how fast a deadpooled block's own premium climbs after it closes, and (15) how fast an open block's own premium climbs across the sample. Writing P_0 for the enrollment-weighted premium at closure, discounting at rate r and weighting each year by survival $s_t = (1-\mu)^t$, the excess a stayer pays over a horizon H is

$$\mathrm{PV}(H) \;=\; \sum_{t=1}^{H} P_0 \left[(1+g_{\mathrm{dp}})^t - (1+g_{\mathrm{cf}})^t \right] \frac{s_t}{(1+r)^t}, \tag{16}$$

with $r = 0.03$ and $\mu = 0.043$ a year. Equation (16) is what Figure 10 plots and what the aging correction of Appendix B adjusts, by replacing g_{cf} with a counterfactual that carries the attained-age gradient.

Figure 10. A Deadpooled Stayer's Premium Grows Three Times Faster than an Open Block's

Notes: This figure contains no simulation output: both growth rates, the starting premium, and the resulting present values are estimated from the NAIC plan-block-year panel via (14)–(16). It is the empirical counterpart to, not a product of, the model of Section 9. Both paths start at $2,603, the enrollment-weighted per-enrollee premium in deadpooling blocks in the year of closure. The deadpooled path grows at the estimated within-block post-closure premium growth rate (7.7%/yr); the counterfactual grows at the within-block premium growth rate in never-closing (open) blocks (2.4%/yr). Both rates are estimated from the plan-block-year panel with block fixed effects and are enrollment-weighted, with standard errors clustered by parent company. Because identification comes from each block's own trajectory rather than from a contrast against never-closing controls, these rates do not rest on the conditional parallel-trends assumption used by the closure event studies. The shaded area is the annual excess premium; its present value, weighting each year by survival at the 4.3% annual mortality hazard and discounting at 3%, is the stayer's excess burden. The 5.3% wedge between the two growth rates compounds, and the shaded area between the paths is what a trapped senior pays for it. Part of the gap is mechanical (a closed block's pool ages while an open block refreshes) and Appendix B nets that out, roughly halving the burden to the headline $5,469 while leaving a substantial deadpooling-specific residual.

We take the aging-netted figure as our headline. Starting from the enrollment-weighted premium at closure ($2,603), a stayer who remains locked in for fifteen years pays an estimated **$5,469** in excess premiums in present value, with the aging-immune benchmark of Table A1 placing a floor at $2,808 and the uncorrected wedge an upper bound of $12,392. All three discount future premiums at 3% and weight each year by survival at the 4.3% annual mortality hazard of a typical Medigap pool. Because the

trapped stayers are precisely the sick beneficiaries who cannot pass underwriting to leave, this per-person figure is the individual counterpart to the concentrated harm that the deadpooling-targeted policy counterfactuals relieve. Figure 10 plots the two premium paths (the shaded wedge between them, summed and discounted, is the excess burden).

Why this measure, and not the loss ratio. The premium a stayer pays rises through two distinct channels, and both are harm. The first is segmentation: as the healthy exit a closed block, the remaining pool's average claims rise, and those claims are passed through to premiums. The second is extraction: the insurer widens its markup, so premiums rise faster than claims. Only the second raises insurer profit, but the stayer pays for both—being sorted into a deteriorating pool is costly to them whether or not the insurer captures the proceeds, and it is deadpooling that does the sorting.

This is why we measure the burden on premiums directly rather than through the loss ratio, and it is worth being explicit about the trade-off, because the loss ratio is the more robust outcome elsewhere in the paper. A loss ratio is claims over premiums, so it is invariant to anything that scales the two together—which is what pool deterioration does. A transfer computed from the loss ratio therefore prices the extraction channel alone and is silent on segmentation, making it a *lower bound* on what a stayer loses. The conversion is also less direct than it appears: because $P = C/\mathrm{LR}$, holding claims fixed at their counterfactual level implies

$$\Delta P \;=\; C\left(\frac{1}{\mathrm{LR}_{\mathrm{dp}}} - \frac{1}{\mathrm{LR}_{\mathrm{cf}}}\right) \;=\; P_{\mathrm{cf}} \cdot \frac{-\Delta \mathrm{LR}}{\mathrm{LR}_{\mathrm{dp}}}, \tag{17}$$

so a loss-ratio change maps into premiums by *dividing* by the post-closure loss ratio, not by multiplying the pre-period premium—a distinction that matters by a factor of $1/\mathrm{LR}_{\mathrm{dp}}$, roughly a third.

The stayer present value is not exposed to this problem, because it reads the burden off premiums and so counts both channels. It is also identified differently from the causal estimates of Section 7.1: (14) and (15) compare each block to its own trajectory through a block fixed effect, not differencing treated blocks against never-closing controls as in (2). The stayer wedge therefore does not rest on the conditional parallel-trends assumption of (3), and the pre-trend tests of (6) reported in Table 2 do not bear on it either way. What it does require is that the open-block trend in (15) is the right counterfactual for a stayer's premium path—an assumption about levels of growth rather than about differences in trends, and the one the aging correction below is designed to discipline. What it does rest on is the aging correction, which is why we report the range alongside the preferred figure and treat Appendix B as part of the estimate rather than as a robustness afterthought.

7.5 Deadpooling Does Not Make the Market Cheaper for Healthy Enrollees

The estimates above price what deadpooling takes from the seniors who stay. They do not say who receives it. If closing a block sequesters the sick and lets the parent open a fresh, cheaply priced successor, then healthy shoppers sort into that successor and deadpooling redistributes between seniors

rather than from seniors to insurers. On that reading a senior has good-deal years while healthy and bad-deal years once trapped, and the practice is a lifecycle reshuffle rather than a net loss. The alternative is that the sorting happens but the discount never does, in which case there are no good-deal years and the practice is simply bad for seniors on both sides of the transaction. This subsection distinguishes the two, and the answer is the second.

Deadpooling does segment risk. Where it is more prevalent, per-enrollee claims are pulled further apart across blocks in the same state, plan letter and year, raising the between-block coefficient of variation of claims by 0.112 (se 0.025, $p < 0.001$). Because deadpooled blocks close and ramp by construction that comparison is close to definitional, so we recompute it among *open* blocks only (the shelf a shopper can actually buy from) where it is 0.129 (se 0.028, $p < 0.001$).

But the sorting does not make the open blocks cheaper. Regressing per-enrollee claims of open blocks on market deadpooling intensity gives \$-19 (se 87, $p = 0.831$) enrollment-weighted—a precise null. Successor blocks do run somewhat healthier pools, but not substantially healthier than blocks whose parents do not deadpool: \$-108 ($p = 0.351$), a difference indistinguishable from zero whose sign flips within parent.

The filings cannot settle the price question, and it is worth being precise about why, because the reason is visible in the claims just quoted. A block's realized average premium in the NAIC data is the average paid by whoever is actually enrolled in it. A fresh block holding a young, healthy pool will post a low average premium at an unchanged price, so a discount and a favorable pool are observationally identical in that measure. The claims confirm that the pools genuinely differ: successors do run healthier. Any comparison of realized premiums between deadpooling and non-deadpooling blocks therefore inherits that selection, and the cheapness of an open deadpooling block in Table 1 is exactly the quantity that cannot be read as a price.

Quoted rates can settle it. The CSG data price the same hypothetical applicant (a non-smoking man or woman of a stated age) at every block on the shelf, so composition cannot move them: two blocks quoting the same applicant differ in price only because they have set different prices. Comparing open deadpooling blocks with open non-deadpooling blocks on that measure, the deadpooling blocks are not cheaper. They are dearer, in every demographic cell we price. At age 65 the quoted rate is 13.6% higher (se 3.6), at 70 6.3% (se 5.3), and at 75 7.9% (se 4.3), lives-weighted, with men's and women's quotes averaged. Table 5 reports these alongside an unweighted version, a saturated specification that compares a block only with blocks quoting the same plan letter in the same state in the same year, and a specification with NAIC company fixed effects. The sign is positive in all twelve estimates, and at 65 every specification but the last excludes zero. Comparing a deadpooling block only with other blocks of the same insurer subsidiary shrinks the gap to 5.7% at 65 and 2.2% at 75, neither distinguishable from zero: most of the premium reflects which subsidiary sells the block. Even within a subsidiary, the deadpooling block is not priced below its siblings at any age.

The two data sources therefore disagree in a way that is itself the answer. Realized premiums say a deadpooling block is cheap while open; quoted prices for a fixed applicant say it is dear. Both are correct

Table 5. Open Deadpooling Blocks Quote Above the Market, Not Below It

	(1) Unweighted	(2) Lives-weighted	(3) Saturated	(4) Company FE
Age 65	9.9%***	13.6%***	12.5%***	5.7%
	(2.7)	(3.6)	(3.2)	(3.6)
Age 70	8.0%***	6.3%	5.1%	2.2%
	(3.1)	(5.3)	(5.5)	(3.0)
Age 75	7.9%***	7.9%*	7.1%	2.2%
	(3.0)	(4.3)	(4.5)	(2.1)
Enrollment-weighted		X	X	X
State, plan-letter, year FE	X	X		X
State × letter × year FE			X	
NAIC company FE				X

Notes: Each cell is the coefficient on an indicator for an open deadpooling block in a regression of the log CSG quoted monthly rate on that indicator, expressed as a percentage difference. Standard errors, in parentheses and also in percentage points, are clustered on the parent (NAIC group). An open deadpooling block-year is a year in which the block is still open to new entrants and the block itself later closes with a successor block opening within five years under the same parent, which restricts treatment to closures through 2020. The comparison group is open blocks that do not meet that definition. Quotes are for non-tobacco applicants and are averaged across ZIP codes within a state. Quotes for men and women are averaged within age. Columns (1) and (2) use additive state, plan-letter and calendar-year fixed effects; column (3) uses a saturated state × plan-letter × year cell, so a block is compared only with blocks quoting the same plan letter in the same state in the same year; column (4) adds NAIC company fixed effects to column (2), so a deadpooling block is compared with the other blocks of the same insurer subsidiary. $^{*}p < .1$, $^{**}p < .05$, $^{***}p < .01$. $N = 48{,}910$ block-years in columns (1) and (2).

descriptions of what they measure, and the gap between them is selection: these blocks attract healthier enrollees without charging them less. The segmentation is real, the discount is not (Figure 11). Nor do deadpooling plans offer a teaser at entry: across attained ages, they quote *above* other plans in the same market, and the gap is no smaller at 65 (Figure 12).

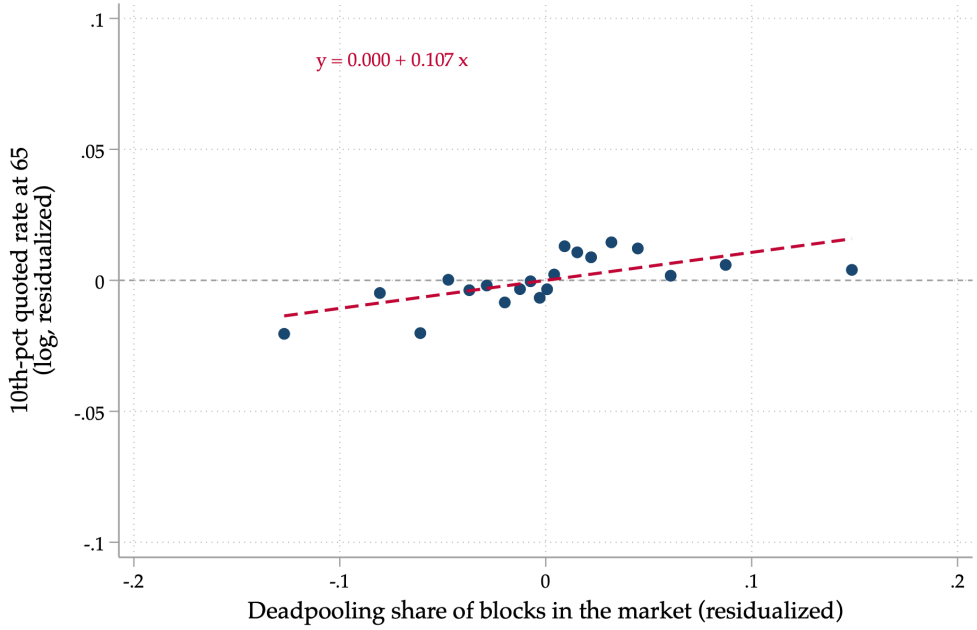

The same holds for the market as a whole, which is what a shopper actually faces. Among states with no switching protections, a market (one plan letter in one state and year) in which more covered lives sit in deadpooling blocks does not offer a lower best price; it offers a higher one. Regressing the log of the cheapest quoted rate for a 65-year-old on the share of the market's lives in deadpooling blocks, with market and plan-letter × year fixed effects and a control for the number of offers, gives a coefficient of 6.6 log points for a move from no deadpooling to all of it (se 2.0, $p = 0.002$; 3,672 markets in 41 states, standard errors clustered by state). The tenth percentile of quotes moves the same way (6.2, se 1.7). A healthy shopper in a deadpooling-heavy market therefore pays slightly more for the cheapest plan on the shelf, not less.

That settles the price a healthy shopper is offered but not the bargain they strike, because the healthy entrant who buys into a successor block is the future trapped stayer. We therefore price the whole path rather than the entry quote: a healthy 65-year-old buys an open block, faces the closure hazard estimated from the panel in each subsequent year, and on closure either escapes to another block at the market price if they can still pass underwriting or rides the ramp if they cannot. A healthy entrant expects to pay $802 more in present value over their remaining lifetime because deadpooling exists. There is an entry discount at which they would be exactly compensated for bearing that risk, and it is 2.1% below the market; successors instead enter 2.5% *above* it. The gap matters for how the practice should be read. A lifecycle bargain that seniors knowingly accept (cheap while healthy, dear once trapped) would

require a price concession at entry, and the market does not make one, so the healthy are not paid for the closure risk they take on. Appendix H reports the calculation and shows that no cell of the hazard, escape-probability and wedge grid reverses the sign.

The distributional reading follows. Deadpooling pulls risk apart without passing the proceeds to anyone but the insurer, which is what one would expect where demand is price-inelastic: Starc (2014) estimates an average own-price elasticity of -1.1 for Medigap and reads it as small, given that standardized plans are close substitutes and so ought to be highly substitutable. There are no good-deal years to set against the bad ones. The transfer runs from the sick to the firm, not from the sick to the healthy, so the equity concern this paper opens with is not offset by a gain elsewhere in the risk distribution.

Figure 11. The Healthy Shopper's Best Price Is No Lower Where Deadpooling Is Prevalent

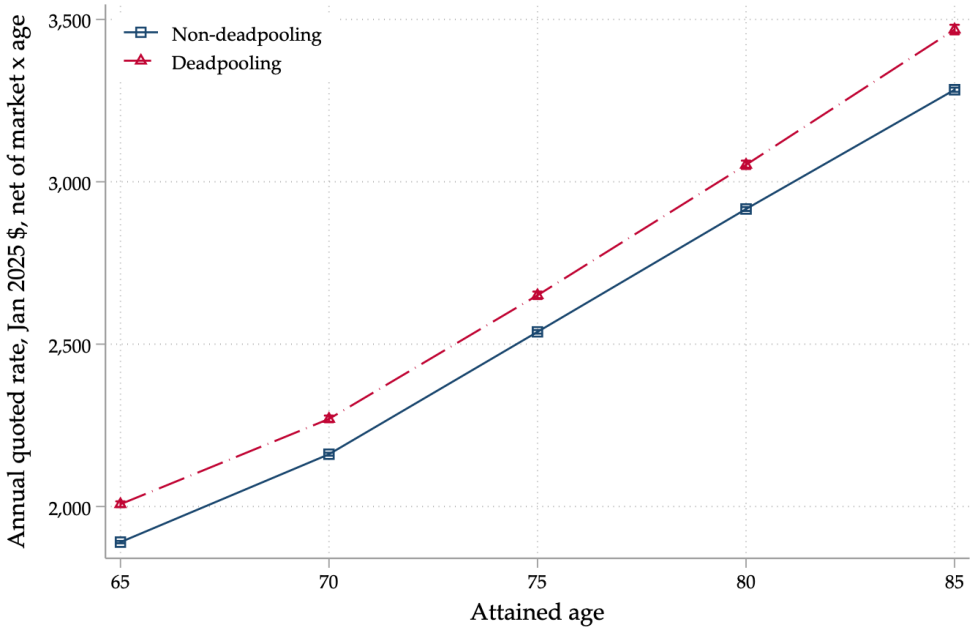

Notes: Market = state × plan letter × year; outcome is the tenth percentile of quoted rates at 65, in logs. Both axes are residualized on market fixed effects, plan × year fixed effects, and the number of offers on the shelf. Binned means, twenty equal-size bins. A downward slope would support the model's assumption that deadpooling churns cheap blocks onto the shelf. Descriptive: deadpooling intensity is not randomly assigned. The slope points the other way: the tenth percentile of quoted rates is 10.6% *higher* where deadpooling is prevalent ($p = 0.035$), as is the cheapest offer (10.1%, $p = 0.051$). The equilibrium object a healthy shopper actually faces is therefore no cheaper, and the artifact-free fixed-draw minimum confirms it (5.3% higher, $p = 0.000$).

8 Policies to Address Deadpooling

While most states have no legislation in place to curb deadpooling, some states require annual periods when beneficiaries can switch plans. This would allow consumers to leave a closed plan when premiums increase, which would at most render deadpooling ineffective and at least transfer the higher premium burden from beneficiaries who would not pass medical underwriting towards beneficiaries who are inattentive or confused about regulations. Opponents of these regulations argue that they make Medigap unprofitable for insurers, degrading the market, and lead to adverse selection (Claassen 2025; Insights 2025).

Figure 12. The Same Age Profile in Dollars: Deadpooling Plans Quote More at Every Attained Age

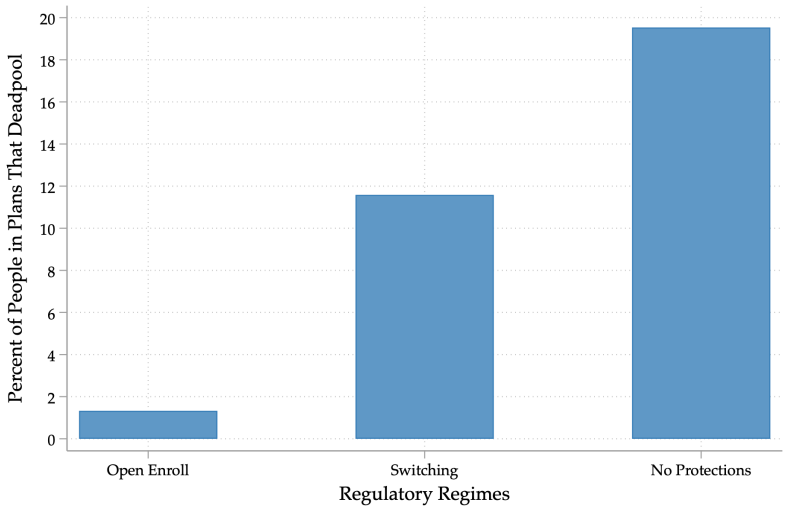

Notes: Mean quoted premium by attained age, deadpooling plans against other plans: CSG quoted premiums for a female, non-tobacco applicant, attained-age plans, 2014–2025, residualized on state × plan × year × age fixed effects. The residual of a log rate is unitless, so this is not a relabelled axis: the age-specific mean log rate is added back onto the residual and the sum exponentiated, which restores the level of the age profile while keeping the market × age netting that makes the two series comparable. Each point is therefore a geometric mean annual rate at that attained age, net of which markets each group sells in, annualized from the monthly quote and deflated to January 2025 dollars. Bands are the exponentiated log-scale 95% interval and are narrow enough to be hard to see at this scale. The log version is retained because the vertical gap there reads directly as a percentage, which a dollar axis cannot do.

8.1 Comparison Across Regimes

Two of these regimes protect switching in different ways, and the distinction matters for who ends up in the pool: a birthday rule lets an existing policyholder move without underwriting, while continuous guaranteed issue also lets someone with no policy buy in at any time. Only the second creates an option to stay uninsured while healthy and buy on falling ill, so only the second should change pool composition rather than merely who holds which policy. Appendix S separates the two, and the data follow that logic: the regime conferring an entry right shifts pool composition by roughly fifteen percent, while the regime conferring only a switching right cannot be distinguished from no protection at all. Deadpooling is far more common where seniors cannot freely switch plans. Figure 13 shows the share of enrollees sitting in a plan that deadpools, by state regulatory regime. In open-enrollment states (New York, Connecticut, and Maine, which guarantee the right to switch Medigap plans at any time) only about 1.3% of enrollees are in a deadpooling plan. That share rises to 11.6% in states with an annual guaranteed-issue switching window and to 19.5% where switching is left to medical underwriting. The ordering is exactly what the lock-in mechanism predicts: trapping and repricing an aging pool is worth much less where enrollees can leave, so firms in flexible-switching states like New York deadpool far less aggressively. This is a descriptive association (a plan is coded as deadpooling if it *ever* deadpools, while the regime is assigned by year) and its causal counterpart is the switching-rule event study (Table 6). The pattern is nearly unchanged when states that altered their regime over the sample are dropped (1.3%, 11.0%, and 19.5%).

Figure 13. Deadpooling Is Far More Prevalent Where Switching Is Restricted

Notes: Share of enrollees in a plan that deadpools, by state regulatory regime, weighted by covered lives and pooled over the sample through 2020 (the years with a full five-year post-closure lookforward). "Open enroll" states (New York, Connecticut, Maine) guarantee the right to switch Medigap plans at any time; "switching" states (e.g. California, Oregon) provide an annual guaranteed-issue window; "no protections" states leave switching to medical underwriting. Deadpooling covers 1.3% of enrollees in open-enrollment states, 11.6% under annual switching, and 19.5% where there are no protections; dropping states that changed regime over the window leaves this nearly unchanged (1.3%, 11.0%, 19.5%). Because a plan is coded as deadpooling if it *ever* deadpools while the regime is assigned by year, this is a descriptive association rather than a causal estimate. Source: authors' calculations from NAIC Medicare Supplement experience filings.

Figure 1 maps the state Medigap regulations in effect during and prior to the period we observe. We

classify these regulations into two categories: open enrollment legislation allows people from outside the Medigap market to purchase a Medigap plan at least annually, while switching legislation allows people already in the Medigap market to switch their policy at least annually. In both cases the right that matters is the right to do so *without medical underwriting*—a beneficiary in any state may always apply to switch, but absent one of these rules the carrier may decline them or rate them up on the basis of health, which is precisely what traps the enrollees this paper studies. Using this classification, we can compare market outcomes across regulatory regimes to assess whether states with stronger switching protections exhibit systematically different levels of premiums, claims, and insurer profits. NY, CT, and ME are the open enrollment states, as they each give Medicare enrollees who do not have a Medigap a chance to join the market at least annually. WA and MO are switching states, as are CA, OR, NV, ID, LA, and IL during the years after they changed their regulations. All remaining states are categorized as having no protections for switching.

Figure A22 depicts average per-person paid premiums, claims, and profits by regulatory regime. The differences between states under switching regimes and states with no protections are essentially zero for all three of these metrics. This is inconsistent with switching regulation generating high levels of adverse selection. As averages may mask important distributional changes, this plot alone cannot distinguish between offsetting reallocations within the market and a true absence of regulatory effects. However, the higher levels of paid premiums and paid claims in the open enrollment states is consistent with adverse selection into the Medigap market under these regulations. As we do not observe any open enrollment regulatory changes, we leave further investigation of open enrollment regulation to future work.

8.2 Event Study

To investigate whether switching rules are successful at reducing deadpooling, we use an event study design. For this analysis to have a causal interpretation, these regulatory changes would have to have been introduced independent of other market reforms. Armour and O'Hanlon (2019) discuss regulatory changes to Medicare Supplement guaranteed issue laws in several states, and they find a number of examples where changes were plausibly exogenous of broader market conditions. For example, Florida and Georgia introduced guaranteed issue rights for beneficiaries under age 65 after activism from Alonzo Mourning (a basketball player for Miami and became a young Medicare beneficiary after a diagnosis of End Stage Renal Disease). Several conversations with agents and policymakers have confirmed that these regulatory changes were not in response to uniquely difficult conditions in the states or years where they were passed.

The estimand, the identifying assumption and the pre-trend test for this design are stated in Section 5.2, alongside their closure-design counterparts.

Table 6 reports the *overall* ATT—the simple aggregation of the ATT(g, t) across post-adoption periods—for each of five outcomes: per-person premiums (Panel A), claims (Panel B), and profits (Panel C), the share of enrollment in deadpooling plans (Panel D), and the loss ratio (Panel E), a

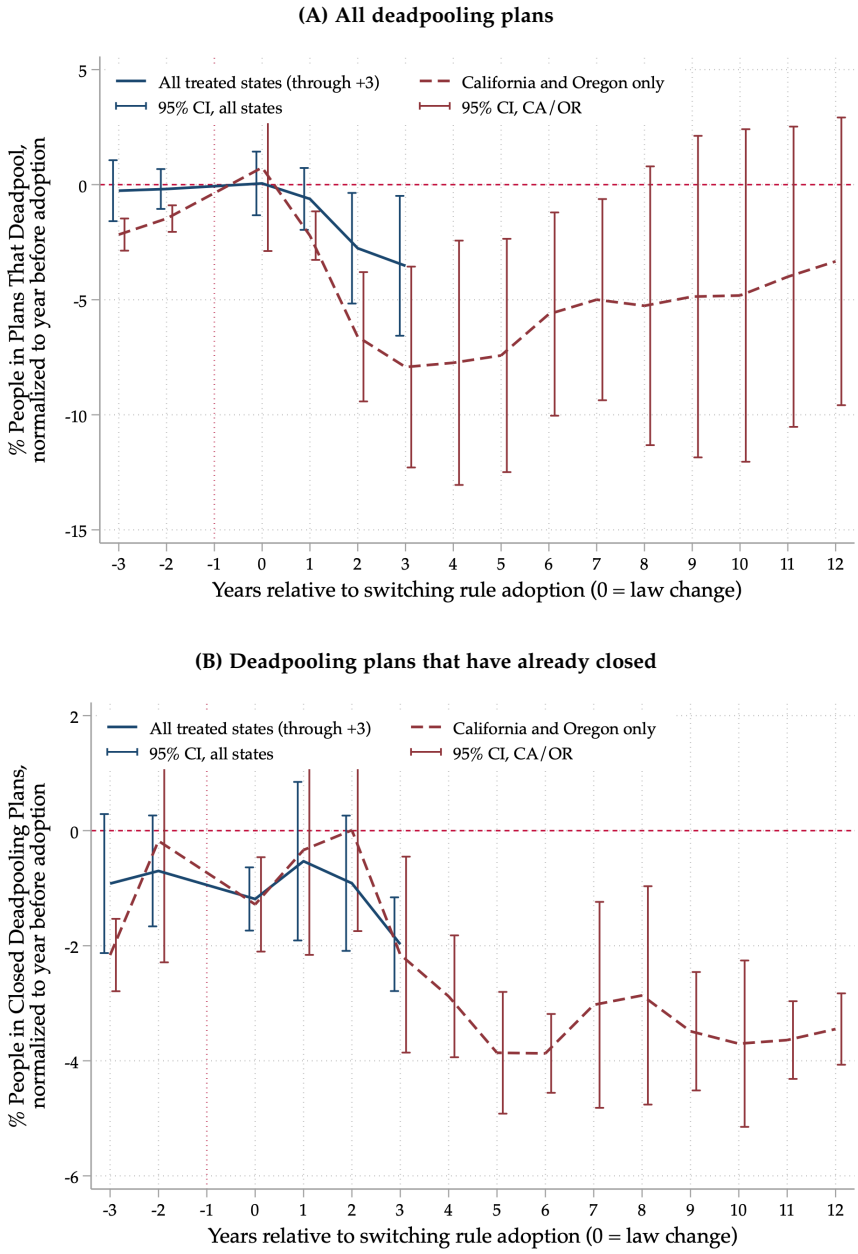

composition-robust price outcome invariant to the enrollment-denominator shift when a block closes. Columns 1–6 estimate each adopting state individually against the never-treated controls (CA 2009, OR 2013, and ID/NV/IL/LA 2022); columns 7–8 pool all six adopting cohorts, and column 8 adds a plan-type doubly-robust adjustment. Figures 14 and 15 plot the same ATT(g,t) aggregated to event time and normalized to the year before adoption ($t = -1$), so the table reports the average post-adoption effect while the figures show its dynamics and pre-trends.

Figures 14 and 15 display Callaway-Sant'Anna event study estimates of the causal effect of switching legislation on per-person premiums, claims, profits, the loss ratio, and the share of enrollment in deadpooling plans, normalized relative to the year of adoption ($t = -1$). Pre-treatment point estimates are generally close to zero and statistically indistinguishable from zero, consistent with the parallel trends assumption. Post-adoption, deadpooling rates decline, while profits, premiums and claims show no clear effect and are heterogeneous across cohorts. A sharp deviation is visible around 2020, driven by the COVID-19 pandemic's effect on healthcare utilization, which caused an outsized and temporary increase in insurer profits across all regulatory regimes. Panel B of Figure 14 refines the deadpooling-share result by restricting to enrollees whose deadpooling plan has *already closed* (the group actually exposed to post-closure premium increases) and shows a comparable post-adoption decline.

The premium panel of Figure 15 is a realized per-enrollee amount, so a null there could in principle be a price effect cancelling against a composition effect. Figure 16 runs the same design on the CSG quoted-price index, which composition cannot move, and finds the same nothing.

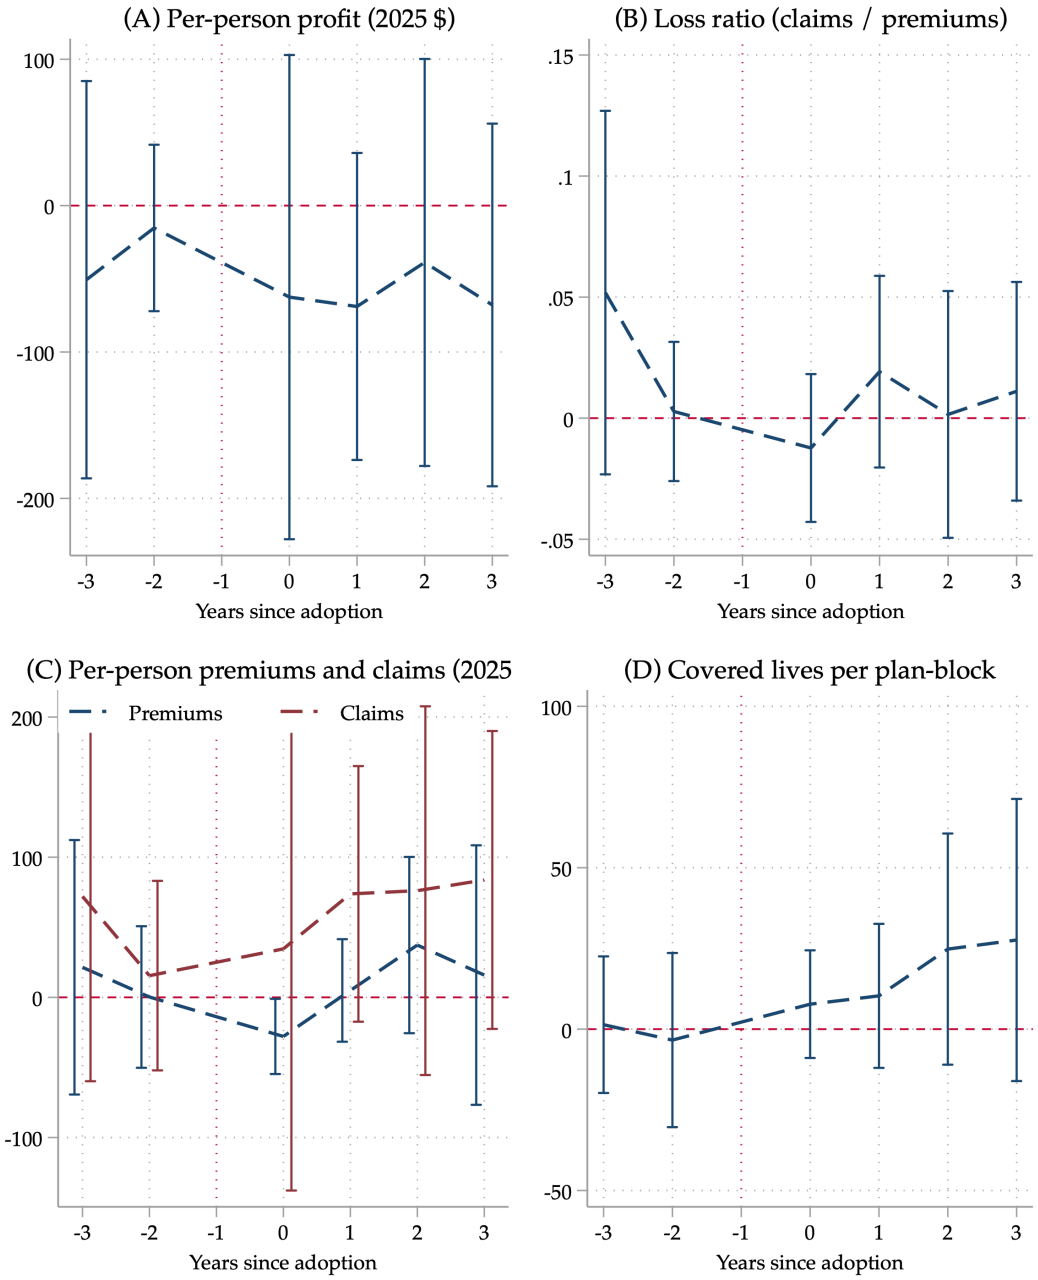

Table 6 reports the Callaway–Sant'Anna overall ATT of switching legislation for per-person premiums (Panel A), claims (Panel B), profits (Panel C), and the share of enrollees in deadpooling plans (Panel D), each estimated against the never-treated states. The individual-state columns (1–6) are noisy (with only six treated states, four of them adopting in 2022, the state-clustered standard errors are wide) and the estimates are heterogeneous: Oregon is again an outlier, with both premiums and profits rising, while the 2022 adopters show small and mostly insignificant premium effects. The pooled columns (7–8) are the more reliable summary. Pooling all six cohorts and adjusting for plan type (column 8), switching adoption moves per-person premiums by \$49.23 per year (s.e. \$102.49, Panel A), an effect indistinguishable from zero, with no significant change in claims (Panel B), and moves the share of enrollment in deadpooling plans by -2.97 percentage points (s.e. 1.84, Panel D), also not significant at conventional levels. The per-enrollee profit effect is positive but statistically indistinguishable from zero (Panel C), so unlike the descriptive within-state associations we find no clear evidence that switching rules erode insurer profitability. A premium increase alongside a fall in deadpooling is consistent with switching rules modestly loosening lock-in while admitting some adverse selection into the market—the pattern the event-study figures above trace out over time. The loss ratio (Panel E), which nets out the enrollment-denominator shift, tells the same story from the cost side: pooled, switching adoption lowers the loss ratio by about 0.04 (insignificant), the mirror image of premiums rising faster than claims, though the individual states are mixed (Nevada's loss ratio rises, Oregon's falls).

Figure 14. Switching Rules Reduce Enrollment in Deadpooling Plans, Including Among Enrollees Already Trapped in a Closed Block

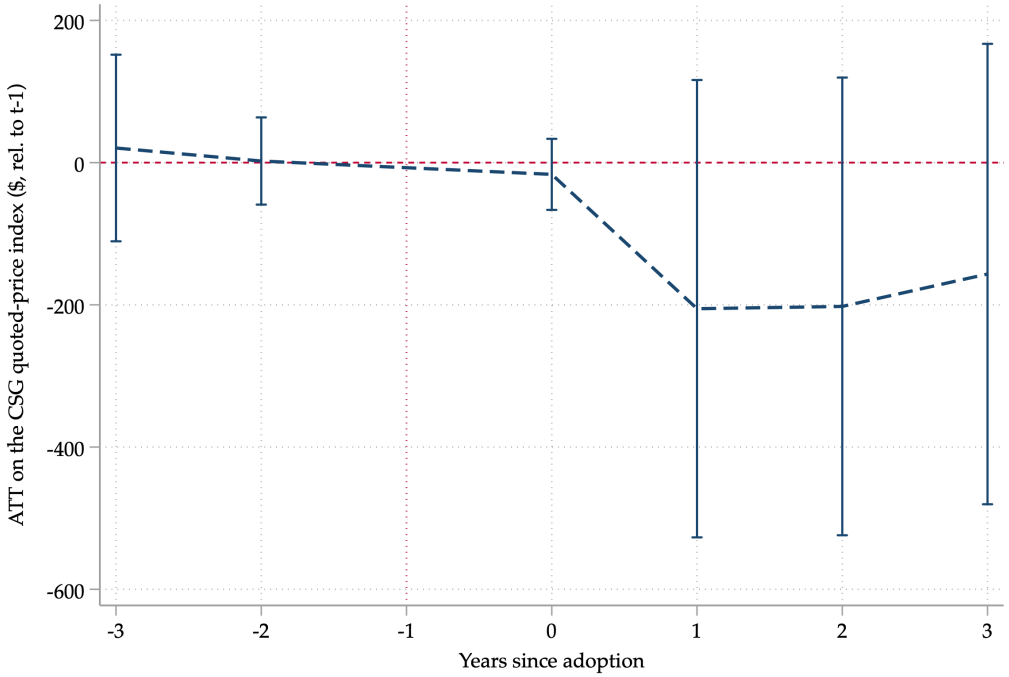

Notes: Both panels are Callaway–Sant'Anna event studies on the same design and differ only in which enrollees the outcome counts. **Panel A** uses every deadpooling plan; **Panel B** narrows to those that have already closed, the group actually exposed to post-closure premium increases. Panel B is a subset of Panel A, so the two are not independent estimates. *Panel A.* Deadpooling is measured as the percent of people enrolled in a plan that deadpools. Event study estimates are computed using the Callaway-Sant'Anna estimator (Callaway and Sant'Anna 2021), with never-treated states as the control group and $t = -1$ as the base period. Estimates are weighted by total lives. This is the clearest evidence that switching rules bind: enrollment in deadpooling plans declines after adoption, by about four percentage points pooled, with no significant pre-trend in the pooled series. *Panel B.* This figure narrows the previous one to the enrollees the policy is actually meant to protect. Panel A counts everyone in a plan that deadpools, including those whose block has not yet closed and who are therefore not yet paying a post-closure premium; Panel B counts only those whose block has already closed, so it measures exposure to the harm rather than exposure to the practice. The outcome is the percent of enrollees in a plan that both deadpools and has already closed (deadpooling block-years in or after the closure year)—the population actually exposed to post-closure premium increases. Callaway–Sant'Anna (Callaway and Sant'Anna 2021) ATT by event time, never-treated states as the control group, normalized to the year before adoption ($t = -1$); estimates are weighted by total lives. The solid navy line pools all six adopting cohorts over $t \in [-3, +3]$; the dashed maroon line is California and Oregon only, estimated across the full $[-3, +12]$ window on its own (rather than spliced on after year three). The dashed horizontal reference marks the mean pre-adoption level of already-closed deadpooling exposure in the adopting states, so the normalized effect can be read against the level it moves. Restricting to enrollees whose deadpooling plan has already closed shows a clear post-adoption decline, so the reduction reaches the population the policy is meant to protect. Joint pre-trend tests on the pooled specification (leads $t-6$ to $t-2$, $t-1$ the base period), state-clustered Wald: no pre-trend test in this figure is significant at the 5% level (the deadpooling share, $p = 0.848$). Under randomization inference over the adoption assignment (199 draws), no test is significant at the 5% level (the deadpooling share, $p = 0.970$).

Figure 15. Switching Rules Leave Premiums, Claims, Profits and Enrollment Unchanged

Notes: Panels are per-person premiums (A), claims (B), profit (C), and the loss ratio (D). Each plots the Callaway–Sant'Anna (Callaway and Sant'Anna 2021) ATT of switching-rule adoption by event time, with never-treated states as the control group, normalized to the year before adoption ($t = -1$, the dotted vertical line). Estimates are weighted by total lives; dollar outcomes are in annual 2025 dollars; the loss ratio is total claims over total premiums (winsorized 1/99), a composition-robust price outcome invariant to the enrollment-denominator shift at closure. The figure shows two *separate* estimates rather than one series restyled partway along. The solid navy line pools all six adopting cohorts and is plotted through $t = +3$, the last event time every cohort reaches. The dashed maroon line re-estimates the same specification on California and Oregon *alone* and is plotted across the whole window, so the two can be compared at $t < 3$ as well as beyond it—the earlier version could not show this, because its dotted tail was the pooled estimate at event times only CA and OR survived to, not a CA/OR estimate. Confidence intervals are offset horizontally so the two sets of caps do not overlap. One caveat governs how much weight the maroon line can bear: with two treated states there are two treated clusters, so its intervals are indicative rather than well-sized inference, and the divergence between the two lines after $t = +3$ should be read as suggestive. Pre-adoption estimates are individually close to zero. The clustered joint test rejects for all four outcomes, but none rejects under randomization inference, the more reliable test with six treated states (see below). Post-adoption, the pooled premium effect is small and imprecise ($49.23 a year with a standard error of $102.49) while claims (B) show no change either, so there is no evidence of a cost pass-through; profit (C) tends to drift down but is pooled-insignificant, so we find no clear evidence that switching rules erode insurer profitability; and the loss ratio (D) falls by about 0.04, the mirror image of premiums rising faster than claims. The sharp 2020 deviation is the pandemic's effect on utilization and appears in every regime. Joint pre-trend tests on the pooled specification (leads $t - 6$ to $t - 2$, $t - 1$ the base period), state-clustered Wald: tests reject at the 5% level for premiums, $p = 0.000$; claims, $p = 0.003$; profit, $p = 0.037$; the loss ratio, $p = 0.024$. Under randomization inference over the adoption assignment (199 draws), no test is significant at the 5% level (premiums, $p = 0.095$; claims, $p = 0.250$; profit, $p = 0.405$; the loss ratio, $p = 0.455$).

Figure 16. Switching Rules Leave the Quoted Price Unchanged Too

Notes: The design of Figure 15 run on the CSG quoted-price index—a fixed (Laspeyres) basket over ages 65–85 weighted by the MCBS age distribution of Medigap holders, in annual 2025 dollars, extended past the end of a closed block's quotes by the closed-block rate increases the carrier filed with the state. Outcomes are collapsed to state × plan-letter × year, which is the level at which the switching rule is assigned, and the ATT is normalized to the year before adoption. Unlike the closure design, no block-level provenance screen is applied to the control side: treatment here varies across *states* and every cell on both sides averages open and closed blocks alike, so screening blocks would drop treated and control cells unevenly across states rather than protect the counterfactual. Because the basket holds the age mix constant, a null here cannot be a price increase offsetting a healthier pool. Joint pre-trend tests on the pooled specification (leads $t-6$ to $t-2$, $t-1$ the base period), state-clustered Wald: no pre-trend test in this figure is significant at the 5% level (the quoted-price index, $p = 0.496$). Under randomization inference over the adoption assignment (199 draws), no test is significant at the 5% level (the quoted-price index, $p = 0.940$).

Census region adj. (DR)			X		X
Pre-period size (DR)				X	X
N (state-plan-yr cells)	8,072	8,072	8,072	8,072	8,072
N (life-years)	154,736,712	154,736,712	154,736,712	154,736,712	154,736,712
ATT(g,t) cells used	114/114	114/114	114/114	114/114	114/114

Notes: Callaway–Sant'Anna (2021) overall ATT (the simple aggregation of the group-time ATT(g,t) across post-adoption periods) of switching legislation, with never-adopting states as the control group, estimated by inverse probability tilting (`drimp`) with a universal base period (`long2`). The two indented row groups of Panel A are the same ATT on two further premium objects: "MF premium, CSG sample" is the realized per-enrollee premium of the row above restricted to the block-years for which a CSG quote exists, and "CSG quoted-price index" is a fixed (Laspeyres) basket over ages 65–85 weighted by the MCBS age distribution of Medigap holders, extended past the end of a closed block's quotes by the closed-block rate increases the carrier filed. So the first two rows differ in their *sample* and the second and third in their *measure*, and because a fixed basket cannot move with the pool, the third is a null that no composition story can explain away. Unlike the closure design no block-level quote-provenance screen is applied here: treatment is assigned at the state level and every cell is a state × plan-letter × year average over open and closed blocks alike, so screening blocks would drop treated and control cells unevenly across states rather than protect the counterfactual. Panels A–C report annual per-person payments adjusted to 2025 dollars; Panel D reports the enrollment share in deadpooling plans, in percentage points; Panel E reports the loss ratio (total claims over total premiums, winsorized 1/99), a composition-robust price outcome invariant to the enrollment-denominator shift when a block closes. All five panels share an identical specification and differ only in the outcome. All five columns pool the six treated cohorts and differ only in the doubly-robust covariates they adjust for, building up from none in column (1) to plan type in (2), plan type and Census region in (3), plan type and pre-period block size in (4), and all three in (5). The panel is collapsed to state × plan-letter × year with enrollment-weighted cell means, matching the state-level treatment; standard errors clustered by state in parentheses. Reading the pooled columns, which are the reliable summary: none of the four pooled effects is statistically distinguishable from zero—premiums \$49.23 (s.e. \$102.49), claims \$10.97 (s.e. \$42.31), profit \$38.26 (s.e. \$114.09), and deadpooling enrollment share −2.97 points (s.e. 1.84). The single-state columns are heterogeneous and noisy (Oregon is an outlier with premiums and profits both rising) which is expected with six treated states, four adopting in 2022. Joint pre-trend tests on the pooled specification (leads $t-6$ to $t-2$, $t-1$ the base period), state-clustered Wald: tests reject at the 5% level for premiums ($p = 0.000$), claims ($p = 0.003$), profit ($p = 0.037$) and the loss ratio ($p = 0.024$); all other pre-trend tests are not significant at the 5% level (deadpooling share $p = 0.848$, CSG quoted-price index $p = 0.496$, premiums on the CSG sample $p = 0.746$). Under randomization inference over the adoption assignment (199 draws) no test is significant at the 5% level (premiums $p = 0.095$, claims $p = 0.250$, profit $p = 0.405$, loss ratio $p = 0.455$). Section 5.3 reports the same tests excluding California.

8.3 Who Uses a Switching Rule?

The fall in the deadpooling share in Panel D of Table 6 raises a question the other panels do not answer. Switching rules do not change how often firms deadpool: the hazard that an open block is closed and replaced does not move after adoption. Nor do they change average enrollment in blocks that were already closed when the law arrived: within such blocks, log enrollment changes by -0.005 at adoption (s.e. 0.049, randomization-inference $p = 0.937$). If the share falls, someone is leaving, and an average over every closed block in every year is the wrong place to look for them. A switching right is worth exercising when the price jumps, not in a typical year.

We therefore ask whether enrollees in closed blocks respond more to *unexpected* premium increases once a switching rule is in force. We measure the unexpected increase as the year-over-year change in the block's CSG quoted-price index, which prices a fixed basket of ages. Because the age mix is held constant, the increase an enrollee can anticipate from moving along the block's own age schedule is excluded, and what remains is the schedule itself moving. We regress the annual change in log enrollment of closed blocks (which take no new enrollees, so enrollment falls only through death, lapse, and switching) on this shock and its interaction with an indicator that the state's switching rule is in force, absorbing block, state $\times$ plan-letter $\times$ year, and years-since-closure fixed effects.

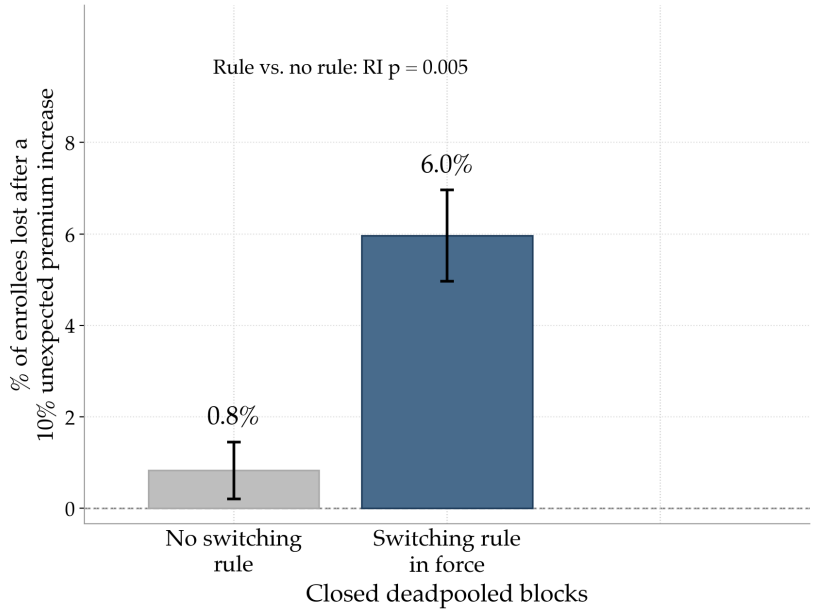

$$\Delta \ln L_{it} \;=\; \beta_1\, x_{it} \;+\; \beta_2 \left(x_{it} \times R_{s(i)t}\right) \;+\; \alpha_i \;+\; \gamma_{s(i)\ell(i)t} \;+\; \delta_{t-G_i} \;+\; \varepsilon_{it}, \tag{18}$$

where L_{it} is enrollment in closed deadpooled block i in year t, x_{it} is the year-over-year change in the log of its CSG fixed-age price index, R_{st} indicates that state s's switching rule is in force (its main effect is absorbed by the state $\times$ plan-letter $\times$ year effects γ), α_i are block effects and δ_{t-G_i} years-since-closure effects; observations are weighted by the prior year's enrollment. A 10% unexpected increase then costs a block $100\,(1 - e^{\beta_1 \ln 1.1})$ percent of its enrollees without a rule and $100\,(1 - e^{(\beta_1+\beta_2)\ln 1.1})$ with one. With six treated states there are too few treated clusters for conventional standard errors, so inference is by randomization over the adoption years (200 draws).

Figure 17 reports the result. In a closed deadpooled block without a switching rule, a 10% unexpected premium increase is followed by the loss of 0.8% of enrollees; where a switching rule is in force, the same increase is followed by the loss of 6.0%. The interaction (-0.56, randomization-inference $p = 0.005$) does not rest on comparing the early adopters with other states: identified only from the change within the four 2022 adopters it is -0.60 ($p = 0.025$) enrollment-weighted and -0.38 ($p = 0.209$) unweighted, although the unweighted estimate pooling all adopters is indistinguishable from zero (0.15, $p = 0.512$). Closed blocks that did not deadpool show no such response (0.21, $p = 0.333$), though the difference between the two kinds of closed block is itself imprecise (-0.21, $p = 0.234$). Mutual of Omaha accounts for 59% of the enrollment-weighted treated sample, and dropping it strengthens the interaction to -1.18 ($p = 0.005$).

The same carrier accounts for the share result. Enrollment is concentrated, so Panel D is moved by a few large books, so we re-estimate its column 7 dropping the largest carriers one at a time. Under

Figure 17. Under a Switching Rule, Enrollees Leave Closed Deadpooled Blocks After Unexpected Increases

Notes: Closed deadpooled blocks. Percent of a block's enrollees lost in the year of a 10% unexpected premium increase, from equation (18): $100\,(1 - e^{\beta_1 \ln 1.1})$ without a switching rule and $100\,(1 - e^{(\beta_1+\beta_2) \ln 1.1})$ with one. The unexpected increase is the year-over-year log change in the block's CSG quoted-price index, a fixed basket of ages 65–85 weighted by the MCBS age distribution, so moving along the block's own age schedule is excluded. The regression is the annual change in log enrollment of blocks closed before the year, enrollment-weighted by the prior year's enrollment, with block, state × plan-letter × year, and years-since-closure fixed effects; sample 2015–2025, individual policies, excluding the states with pre-existing switching or open-enrollment rules. Bars show 95% intervals from state-clustered standard errors, which rest on six treated clusters; the annotated p-values are for the rule interaction by randomization inference, reassigning the six adoption years to random never-adopting states (200 draws). Section 8.3 reports the specification identified only from the 2022 adopters, the unweighted estimates, and the estimate without Mutual of Omaha.

randomization inference the pooled decline is itself distinguishable from zero (-2.89 points, $p = 0.045$). Dropping UnitedHealthcare, which does not deadpool, leaves it intact (-3.52, $p = 0.124$). Dropping Mutual of Omaha, which holds 49% of its enrollment in deadpooling blocks, reverses its sign (1.23, s.e. 0.59). In the four 2022 adopters, enrollment in Omaha's closed deadpooled blocks fell from 51.9 thousand in 2022 to 30.6 thousand in 2025, while its successor blocks, which are not yet classified as deadpooling because they have not closed, took on enrollment. Over the same post-adoption window UnitedHealthcare's share of enrollment rose by 3.9 points (s.e. 1.5).

Two cautions apply. Part of the Omaha decline is the deadpooling cycle itself: Omaha closed its largest Illinois and Nevada blocks the year before those states' rules took effect, and a closed block drains whether or not a law passes. And six treated states, with one carrier carrying the share result, are a thin basis for precise magnitudes. We therefore read this as supporting evidence rather than a headline. Switching rules do not stop firms from deadpooling, but enrollees trapped in closed deadpooled blocks do use the right when a large unexpected increase arrives, and enrollment shifts toward a carrier that does not deadpool.

Increases of this size are common: 22.7% of closed deadpooled block-years see a rise of 10% or more in the CSG fixed-age price, lives-weighted, against 10.7% of open block-years. And the response is small next to what a fully attentive enrollee would do. In switching-rule states, every enrollee hit by such an increase had a cheaper open plan of the same letter at their age (100% of the 33 block-years), on average \$1,413 a year (40% of the premium) cheaper, and 100% already had one the year before the increase; about 6.0% leave.

8.4 Do Switching Rules Drive Insurers Out of the Market?

Opponents of switching legislation argue that it makes Medigap unprofitable, thins the set of carriers, and ultimately degrades the market (Claassen 2025; Insights 2025). If that were so, adoption should be followed by insurers leaving—subsidiaries withdrawing their books, parents pulling out of the state, and the number of carriers on the shelf falling. We find no such response on any of these margins, in the data or in the model.

Consider first whether insurers withdraw. We distinguish two distinct insurer actions the NAIC records separately. *Closure* stops new enrollment but keeps covering existing members—the first step of the deadpooling cycle studied above. *Withdrawal* is a true market exit: the insurer stops covering current members, which triggers a special enrollment period for them. The filings carry a withdrawal date separate from the closure date, and we build a plan-level withdrawal indicator from it and run the same Callaway–Sant'Anna switching-adoption design used above. The lives-weighted withdrawal rate does not move: the overall ATT is *essentially zero* (about 0.01 percentage points, s.e. 0.06), with flat pre-adoption trends and no significant effect at any horizon. The closure rate is likewise statistically unchanged (ATT about 0.9 points, s.e. 0.8). Insurers neither exit nor accelerate closures when switching rights arrive.

The carrier count tells the same story. Counting active subsidiaries and parents per state-year and

running the same design, we find no post-adoption decline over the window in which all six adopting cohorts contribute (event years 0 to +3): the point estimates are small and, if anything, slightly positive, against flat pre-trends. Negative estimates appear only at event years +4 and +5, which are identified off California and Oregon alone (the 2022 cohorts do not yet reach that far) and, for carrier counts measured by mere presence, sit on top of a pre-adoption downward trend; we do not read them as a causal effect of the policy. A purely cross-sectional comparison across regimes does show fewer carriers under more protective rules—open-enrollment states average about 14 parents with an open block against roughly 31 in switching states and 34 in unprotected states, while the annual withdrawal rate is if anything *lower* under more protection (0.01%, 0.09%, and 0.16% of covered lives, respectively). But that ranking reflects *which* states adopted (the open-enrollment states are the small NY/CT/ME markets) rather than an effect of the regime, which is exactly the between-state confound the event study nets out. Within a state, switching adoption does not shrink the carrier count.

Taken together, switching rules loosen lock-in without driving carriers out of the market. Section 9.3 shows the same holds inside the model, where no policy regime we simulate makes the business unprofitable; the market-degradation argument is not borne out.

9 Model and Policy Simulation

9.1 Model Overview

We build a simulation of beneficiary and insurer behavior in the Medigap market. This allows us to comment on some topics the existing data does not. The reduced-form results are local and partial-equilibrium: they measure what a deadpooled block does to its own enrollees, holding the rest of the market fixed. Three questions of interest lie outside that frame.

The first is the decomposition of deadpooling profit into selection and rent—whether the strategy pays because fresh blocks skim the healthy or because trapped enrollees are marked up—which requires observing each enrollee's true health, and so is available in the model and nowhere in the filings. The second is the division of the harm between transfer and destroyed surplus. The data show what a trapped enrollee pays; only the model says how much of that is redistribution to insurers and how much is surplus no one captures, which is what reveals that a policy can end the transfer and leave consumers no better off. The third is the set of policies no state has tried: a ban on closures, and reforms that act on consumer attention rather than on switching rights. Attention is a margin the model can vary directly, which lets us ask how much of a reform's efficacy is limited by inattention rather than by the rules themselves—a question the panel cannot pose, because no policy has ever moved it.

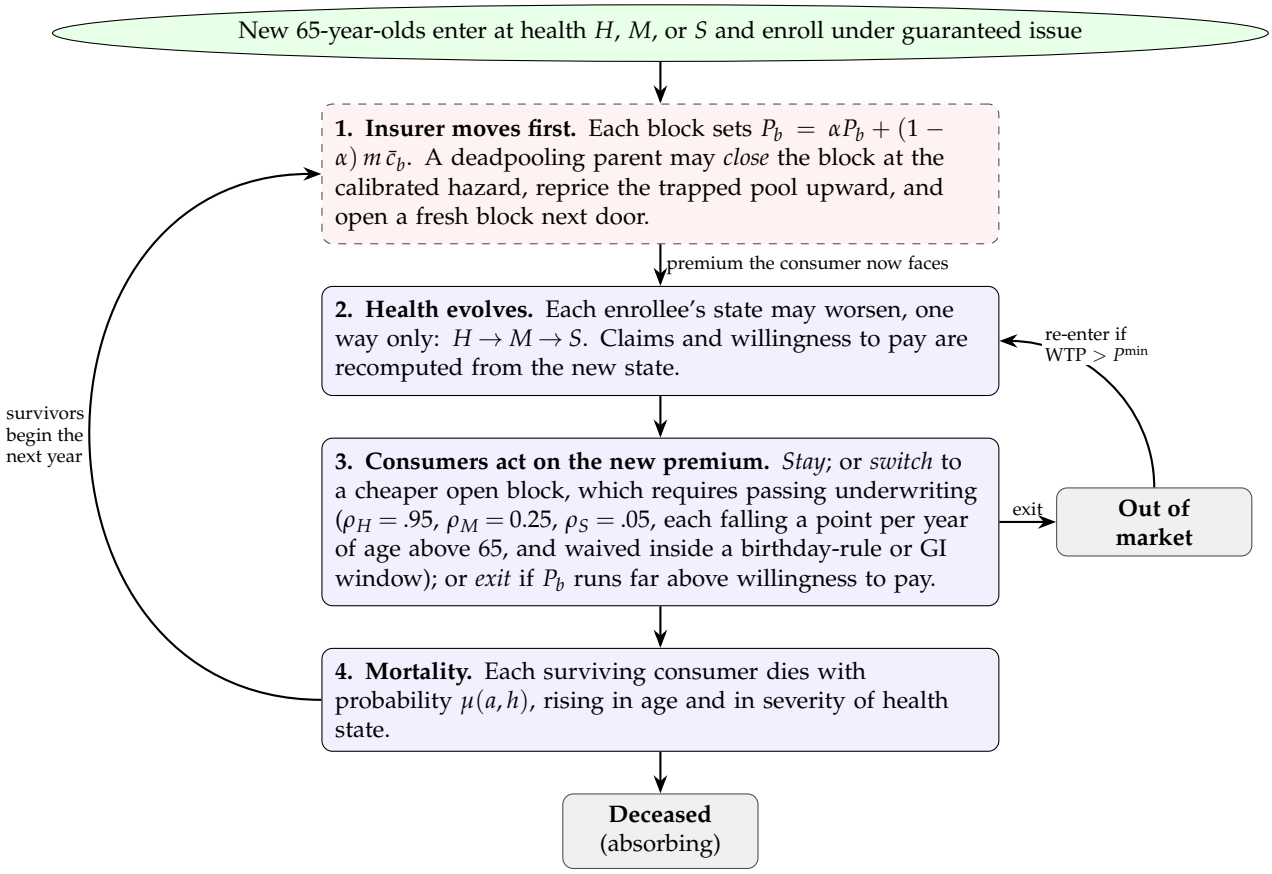

We calibrate the model to moments of the observed market and then simulate counterfactual policy regimes from the calibrated steady state.

9.2 Model Setup

The market consists of a set of F parent insurance companies, each operating across S states and offering L standardized plan tiers, whose claims and premium levels are calibrated so that the market in aggregate matches the aggregate Medigap market during our period. Each company–state–plan-tier triple defines a *block*: a group of enrollees sharing a risk pool, so there are up to $F \times S \times L = 555$ active blocks at any time. Appendix U.8 gives the values we use and shows that the calibrated moments and profit are insensitive to raising the number of companies and states, so they are a computational convenience rather than a substantive assumption.

The model period is one year. Each period, insurers update premiums and may close a block, enrollees' health evolves, enrollees decide whether to stay, switch, exit, or re-enter, mortality is realised, and new 65-year-olds enroll; Figure 18 sets out that order of events.

Figure 18. The Order of Events Within a Model Year

Notes: The figure reads top to bottom as one model year, in the order the model executes it. The dashed box is the insurer's move and it comes *first*: each block prices as a markup over its prior-year claims and, if its parent is a deadpooling type, may close at the calibrated hazard, repricing the trapped pool upward and opening a fresh block next door. Health then evolves, one way only ($H \to M \to S$), and claims and willingness to pay are recomputed. Only then do consumers act on the premium they now face (staying, switching to a cheaper open block if they pass underwriting, or exiting if the premium runs far above willingness to pay) after which mortality is realised and the survivors begin the next year at the top. Ordering matters for the mechanism: because the insurer moves first, the price a trapped enrollee reacts to is already the post-closure one, and the enrollees best able to leave are the healthy, which is what deteriorates the pool that remains. Consumers out of the market may re-enter if a premium falls below their willingness to pay and they pass underwriting. Underwriting pass rates (ρ_H, ρ_M, ρ_S) fall a further point per year of age above 65, so sick and older enrollees are effectively locked in.

Each consumer enters at age 65 with one of three health states (healthy, moderate, sick) that can worsen

over time, and a willingness to pay (WTP) for coverage equal to the certainty equivalent of their future claims: the expected present value of claims over a forward simulation, plus a risk premium reflecting aversion to the variance in those claims. Consumers also have a price-sensitivity index $\lambda_i \sim \text{Beta}(0.60, 2.40)$, placing most mass near zero. We use a Beta because the index is a bounded attention parameter on $[0, 1]$ (zero is a consumer who never shops, one is a consumer who always takes the cheapest offer) and the Beta is the natural two-parameter family on that support, flexible enough to be calibrated to both the average shopping rate and its concentration near zero without allowing mass outside the interval. [19] Each year, a consumer enrolled in a plan makes one of two choices. They may shop and switch to a cheaper open block, which requires passing medical underwriting; or they may drop coverage altogether, which they do if their premium comes to exceed their willingness to pay by enough. A consumer who is out of the market faces a different decision: they may re-enter if a premium falls below their willingness to pay, but re-entry is also subject to underwriting, so a consumer who has fallen ill since leaving may be unable to return. Sick consumers are effectively locked in to the plan in which they first enroll, by both high WTP and low underwriting pass rates ($\rho_S = 0.05$).

Each block sets a community-rated premium as a markup over its own most recent claims experience:

$$P_b^{t+1} = m_b \cdot \bar{c}_b^t, \tag{19}$$

where $\bar{c}_b^t$ is block b's average claims per enrollee in the preceding year, so a block prices off realised experience rather than contemporaneous cost. Premiums are therefore set in accordance with the loss ratio: a block marks up the claims it has just paid, and the markup is what the observed premium-to-claims ratio implies. Deadpooling plans impose an additional markup term for each year a block has been closed. Deadpooling insurers close blocks to new enrollment and open new blocks under subsidiaries. Blocks under deadpooling parents have a chance of closing each year based on how long they have remained open, estimated from the NAIC panel and applied only to the 14% of parents designated deadpooling types.[20] Once closed, healthy consumers exit to open blocks while sick consumers remain trapped, deteriorating the risk pool, raising premiums, and deepening the adverse selection spiral.

Additional model details are in Appendix U.

The model is calibrated by grid search to ten moments of the Medigap market: the average premium and average claims of open and of deadpooled-closed blocks, the share of enrollees sitting in a closed deadpooled block, the four-point post-closure retention curve, and the annual rate at which enrollees leave Medigap. Three parameters are free (the share of parents that deadpool, the scale of the closed-block markup ramp, and the responsiveness of exit to price); the open-block markup is pinned from the data so that a fitted markup cannot absorb the loss ratio. Table A3 in Appendix D reports the

19. We justify this choice using results from a study we ran with the Understanding America Survey; 68% of UAS enrollees consulted only one agent at enrollment, and 73% have never switched, suggesting that many people do not shop aggressively in this market.

20. Treating the hazard as exogenous to the individual block is supported by the closure evidence: closures are coordinated, subsidiary-wide events, with a subsidiary's closures clustering across plan letters and across states within a single year, so the timing is a corporate decision rather than a response to any one block's pool or market conditions (Appendix G).

fit. Prices and the closed-block share match closely; post-closure retention is the weak point, and the model empties closed blocks too slowly, which biases its lock-in duration and any harm figure integrating over it *upward*. Appendix D gives the targets, the three primitives re-derived for this draft, and the limitations in full.

9.3 Counterfactual regimes and aggregate effects

To complement the empirical evidence, we take the calibrated model exactly as described above and change only the rules of the market, leaving every primitive, parameter and calibration target fixed. Each counterfactual below is therefore the same market and the same consumers under a different regulatory regime, and any difference between regimes is attributable to the rule change rather than to a re-tuned model. We report steady-state effects. The baseline calibrates to match empirical moments from states without guaranteed-issue or birthday-rule protections on the 2025 NAIC panel. We compare demand-side switching policies—a birthday rule (underwriting waived for plan switches once per year) and continuous guaranteed issue (underwriting waived for all enrollment decisions)—a supply-side ban on deadpooling (a direct prohibition on closing blocks to new enrollment), and consumer-attention counterfactuals in which every consumer's price sensitivity is scaled up (savvy consumers), alone and combined with each of the two switching policies.

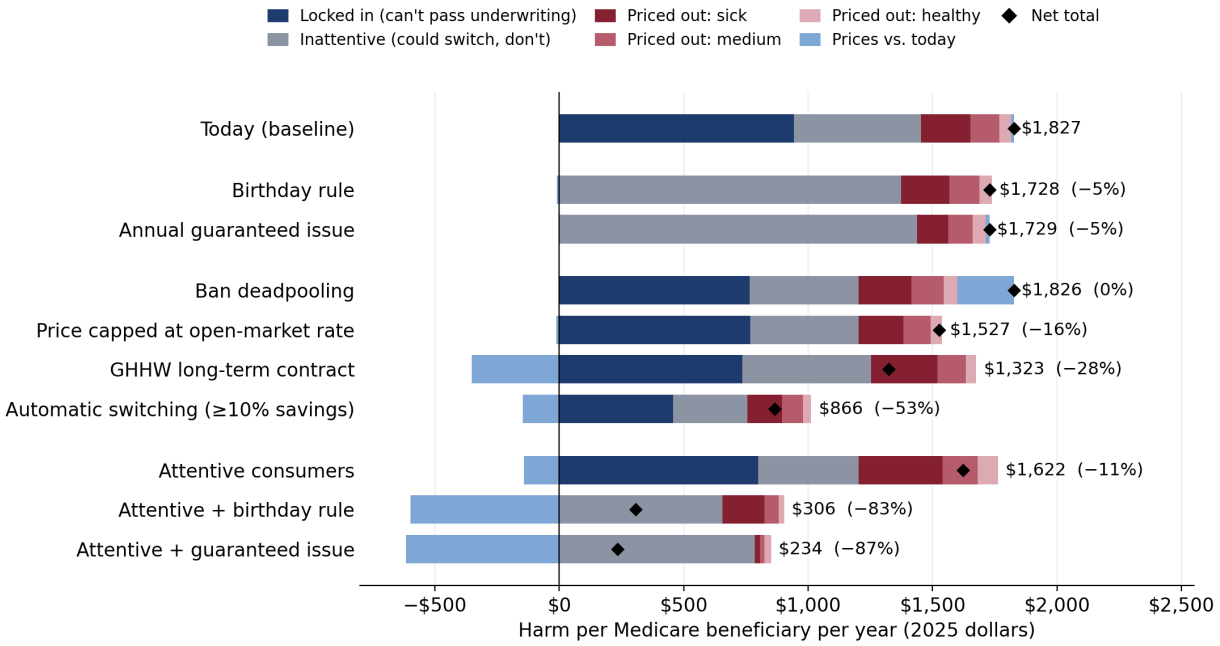

At baseline 10.8% of enrollees sit in a closed deadpooled block. An outright ban on closures empties those blocks almost entirely, to 0.0%; the switching policies do considerably less, cutting the trapped share to 9.5% under a birthday rule and 7.9% under continuous guaranteed issue. A switching right is only as good as the enrollee's willingness to use it, and at baseline attention most trapped enrollees do not move even once the underwriting barrier is lifted. Aggregate premiums and profits move very little under any of the three: the average premium changes by $-\$5$ under the birthday rule, $+\$48$ under guaranteed issue and $-\$13$ under the ban, against a baseline of \$2,862, while per-enrollee profit stays within \$20 of its \$571 baseline. Market-wide averages are thus nearly unchanged even where the affected high-risk enrollees gain sharply, which is what makes deadpooling a concentrated rather than an aggregate harm. The consumer-attention counterfactuals move the aggregates most, and only in combination: raising price sensitivity on its own leaves premiums essentially flat ($-\$178$), because attentive enrollees who still cannot pass underwriting leave the market rather than move within it, whereas pairing it with a birthday rule moves the average premium by $-\$181$ and profit by $-\$51$—the largest change of any regime, and still only 116% of baseline profit.

9.4 Where the Harm Goes and Whom It Hits

The transfer measures what insurers collect from enrollees trapped in closed blocks; it does not see anyone outside one. Figure 19 therefore scores every living beneficiary in the model against a common yardstick, the cheapest open premium r in their market under the baseline rules. Harm is the surplus a person would have at that price, $\max(\text{WTP} - r, 0)$, minus the surplus they have (willingness to pay net of premium if enrolled, zero if not), and it splits exactly into four sources: people priced out of a plan

they value above r; enrolled people paying more than the cheapest open plan, divided by their probability q of passing underwriting into those who are locked in (weight $1 - q$) and those who could switch but do not (weight q); and the change in open premiums themselves. Under the baseline, harm is $1,827 per beneficiary per year, of which $943 is lock-in and $511 inattention. Switching rights convert the first into the second: under a birthday rule lock-in falls to $0 while inattention rises to $1,373, so total harm falls by 5%. A ban changes total harm by 0%, because lock-in falls but open premiums rise by $227 once the low-priced successor blocks disappear. Automatic switching cuts harm by 53% with no change in attention, and attention combined with a switching right cuts it by 83–87%. Because the yardstick is the same in every regime, ranking regimes by total harm is the same as ranking them by consumer surplus per living beneficiary.

Figure 19. Harm per Beneficiary Under Each Reform, and Where It Comes From

Notes: Harm per living Medicare beneficiary per year in the calibrated model, January 2025 dollars, steady state (years 60–79, four seeds). Each person is scored against the baseline's cheapest open premium r in their state, plan letter and year; harm $= \max(\text{WTP} - r, 0) - \text{CS}$. Each segment is one source's total divided by all living beneficiaries, so the segments sum to the total (diamond, with the percent change from today). *Locked in* and *Inattentive*: premium paid above the cheapest open plan, weighted by one minus and by the underwriting pass probability. *Priced out*: out of Medigap with WTP $> r$, by current health. *Prices vs. today*: change in the cheapest open premium, negative when open plans are cheaper than today.

Figure 19 divides each source by every living beneficiary. Table 7 divides it instead by the people it actually hits, with the share of beneficiaries affected in parentheses; locked-in and inattentive heads are expected counts, weighted by $1 - q$ and q as the dollars are. Under the baseline, a sick person priced out of Medigap loses $2,712 a year (7.2% of beneficiaries), and a locked-in enrollee overpays $2,169 (43.5%). Across regimes, the reforms mostly change *how many* people are hurt rather than how much each affected person loses.

A vote. A simple way to summarize the distribution is to ask which policy the model's population would choose. We group everyone alive in the last simulated year into types by health, attention and age band; each type votes for the policy that gives people of that type the highest average consumer surplus

Table 7. Harm per Affected Person, by Source and Regime

	Priced out				
Regime	Sick	Medium	Healthy	Locked in	Inattentive
Today (baseline)	\$2,712 (7.2%)	\$1,876 (6.3%)	\$688 (6.9%)	\$2,169 (43.5%)	\$1,891 (27.0%)
Birthday rule	\$2,741 (7.1%)	\$1,885 (6.4%)	\$712 (7.2%)	—	\$1,999 (68.7%)
Annual guaranteed issue	\$2,626 (4.8%)	\$1,829 (5.4%)	\$715 (7.1%)	—	\$2,006 (71.6%)
Ban deadpooling	\$2,721 (7.8%)	\$1,881 (6.9%)	\$712 (7.7%)	\$1,806 (42.4%)	\$1,639 (26.6%)
Price capped at open-market rate	\$2,737 (6.6%)	\$1,877 (5.8%)	\$693 (6.6%)	\$1,725 (44.5%)	\$1,584 (27.5%)
GHHW long-term contract	\$2,410 (11.0%)	\$1,586 (7.3%)	\$643 (6.4%)	\$1,923 (38.2%)	\$1,835 (28.3%)
Automatic switching ($\geq$10%)	\$2,751 (5.1%)	\$1,886 (4.4%)	\$682 (4.9%)	\$1,462 (31.3%)	\$1,470 (20.3%)
Attentive consumers	\$2,517 (13.4%)	\$1,672 (8.4%)	\$897 (9.2%)	\$2,439 (32.8%)	\$2,152 (18.8%)
Attentive + birthday rule	\$2,507 (6.7%)	\$1,678 (3.5%)	\$946 (2.3%)	—	\$2,640 (24.8%)
Attentive + guaranteed issue	\$1,996 (1.0%)	\$1,543 (1.3%)	\$930 (2.8%)	—	\$2,662 (29.5%)

Notes: Harm per affected person per year in the calibrated model, January 2025 dollars, same run and yardstick as Figure 19; in parentheses, the share of living beneficiaries affected. *Priced out*: out of Medigap although they value it above the baseline's cheapest open premium, by current health. *Locked in* and *Inattentive*: paying more than the cheapest open plan, with heads weighted by one minus and by the underwriting pass probability. —: no one affected.

in that year (counting those out of Medigap at zero), and votes are weighted by the number of living people of each type. Among the regimes in Figure 19, Attentive + birthday rule wins with 81% of the vote and beats every alternative head to head. Attention, however, is not something a regulator can legislate; restricting the menu to rules that can be imposed directly, Automatic switching ($\geq$10% savings) beats every alternative, with at least 100% of the vote in each head-to-head comparison. A ban on deadpooling would not command a majority against the status quo: 46% of the population is better off under it. Because the branches of the simulation consume random numbers differently after the policy switch, the same person is not comparable across regimes, which is why voters are types rather than individuals.

10 Conclusion

The Medicare Supplement market insures almost 14 million beneficiaries in plans that cost thousands of dollars a year out of pocket. Because Medigap is a high-quality product sold to a population whose health deteriorates predictably, most states shield it from adverse selection through lock-in: after an initial enrollment window insurers may underwrite applicants, so a beneficiary who falls ill cannot readily move. Lock-in solves one problem and creates another. It hands whichever insurer first enrolled a beneficiary a durable measure of market power over them, and this paper is about what firms do with that power.

What they do is not what the regulation anticipated. A parent closes a block to new members, lets the surviving pool age and sicken, raises its price against enrollees who can no longer pass underwriting elsewhere, and opens a fresh block through a separate subsidiary to gather the healthy applicants the closed block can no longer attract. Both blocks belong to one firm; only the ownership linkage reveals it. We show that closure raises premiums well beyond what claims justify, that the increase is larger where the parent reopens than where it does not, and that closures arrive as coordinated, subsidiary-wide

events rather than as independent responses to block-level cost shocks—the signature of a strategy rather than of misfortune. The practice does not make the market cheaper for healthy shoppers, either: successor blocks are not quoted below comparable new entrants at any point in their lives, so the rent extracted from the trapped is not competed away on behalf of anyone else.

The harm is large and concentrated. 17.6% of Medigap life-years through 2020 are spent in a plan that deadpools, and the practice transfers an estimated $298.6 million a year from seniors to insurer profits, $5.7 billion across our sample period. It falls hardest on those least able to escape it: premiums in a deadpooled block grow 7.7% a year against 2.4% in blocks that stay open, and a trapped stayer pays that widening gap for as long as they hold the policy (Section 7.4). Part of that gap is the pool simply aging; netting aging out, a fifteen-year stayer in a state without switching rights still pays $5,469 more in present value than in a block that stays open. Counting the enrollees driven out of coverage entirely, and not only the transfer paid by those who remain, each dollar of deadpooling profit costs seniors $2.28. Because that figure is a ratio it moves inversely with the profit estimate scaling it—attributing more of the premium increase to profit rather than to claims shrinks the excess burden per dollar of profit without changing the burden itself.

The regulatory record is mixed in an instructive way. Open enrollment periods curb the practice effectively but expose the market to the adverse selection lock-in was meant to prevent; switching rules avoid that exposure but deliver more modest reductions. Price dispersion persists under both: in New York a 65-year-old man is quoted between $293 and $613 for identical Plan G coverage, and across the panel deadpooling raises the between-block dispersion of claims among open blocks by 0.129 (se 0.028). The calibrated model explains why no single instrument suffices: escaping a deadpooled block requires both the *right* to switch and the *attention* to notice one should. Measured as harm per Medicare beneficiary—the surplus each person loses against today's cheapest open plan—a birthday rule removes 5% of it and raising consumer attention alone 11%, but the two together remove 83%: they are complements, not substitutes. A direct ban removes 0%: it frees the locked-in, but open premiums rise once the cheap successor blocks disappear. Among rules a regulator can impose without relying on attention, automatic switching does the most, removing 53%.

A further cost sits outside the transfer accounting above. Medigap's first-dollar coverage raises total Medicare spending, because an enrollee facing no cost sharing uses more care (Cabral 2017). That is a real social cost, and it is one deadpooling does not create but does help sustain: a practice that keeps the supplemental market profitable keeps the utilisation it induces in place. It is worth saying plainly that the comparison class has the same problem. Medicare Advantage raises program spending by a broadly similar magnitude, though through a different combination of channels—utilisation alongside more intensive diagnosis coding, which raises risk-adjusted payments without raising care delivered. Medigap's increase runs through utilisation alone. Neither the case for nor the case against supplemental coverage turns on deadpooling, but a reader weighing the practice against the alternatives should know that eliminating it would not by itself reduce what Medicare spends.

Three broader questions follow. The first is about the unit at which regulation binds. Every rule here is

written for a licensed entity, while the decision is made by a parent that owns many of them, so a firm can comply at each entity and evade in aggregate; wherever corporate structure is cheaper to rearrange than conduct is to change, this gap will reappear. The second is about the price of solving adverse selection with lock-in. Contracts that hold consumers in place to keep pools stable also make those consumers durably capturable, and the resulting hold-up is not merely theoretical—it is a measurable transfer here, borne by the sick. The third is about what consumer choice can be asked to accomplish. Choice-based remedies presume a consumer who monitors prices and acts on them, and in a market whose enrollees are elderly, whose contracts are long-lived, and whose repricing is gradual, that presumption is where the remedy fails rather than where it succeeds.

Out-of-pocket limit**	N/A	N/A	N/A	N/A	N/A	N/A	$7,060 in 2024	$3,530 in 2024	N/A	N/A

Source: Centers for Medicare & Medicaid Services, *Choosing a Medigap Policy: A Guide to Health Insurance for People with Medicare* (CMS Product No. 02110), medicare.gov. *Notes:* The ten lettered plans are fixed by statute, so any two plans of the same letter cover identically regardless of insurer. Benefit design is therefore not a margin on which insurers compete, which is what makes the price dispersion documented below (over $300 per month for identical coverage) difficult to attribute to product differences.

B Appendix: Netting Out Aging from the Stayer Burden

Section 7.4 reads a trapped stayer's burden off the growth of a closed block's per-enrollee premium. This appendix nets out the part of that growth that is the pool aging.

The aging confound, and how far it goes. A closed block issues no new policies, so its mean attained age rises by about a year every year; an open block refreshes with new sixty-five-year-olds and holds its mean age roughly flat. Under attained-age rating the closed block's *pool-average* premium therefore rises even if the insurer never raises a single rate, and the block-level wedge $g_{\text{dp}} - g_{\text{cf}}$ mixes this mechanical aging drift together with adverse retention and with genuine rate increases. The aging drift, crucially, is *not* deadpooling-specific harm: a trapped stayer would have aged along the same rate schedule in an open block too, so the excess a stayer pays *because* the block deadpooled should net it out. We bound how much of the wedge it accounts for.

The design exploits rating type. Community-rated and issue-age plans are immune to the individual aging gradient by construction (a community-rated premium does not vary with age, and an issue-age premium is fixed at the age of purchase) whereas an attained-age premium climbs as the enrollee ages. Rating type is not randomly assigned, however: open-market states are almost entirely community-rated, and stronger switching protection correlates with community rating, so a raw comparison across rating types would confound aging with the regulatory regime. We therefore hold the regime fixed and run the entire comparison *within* the

no-switching (maximal lock-in) regime, which is the relevant regime for a trapped stayer and which contains all three rating types. Within it, the raw attained-age wedge is 4.7 percentage points a year. Netting out only the individual age gradient—which we read directly off the CSG quoted-rate curve as 2.8 points per year of age, and which is *identical* for deadpoolers and non-deadpoolers (2.8 points, insignificant net of state, plan, and year fixed effects, with no steepening after closure)—leaves a deadpooling-specific wedge of 2.0 points. Because the attained-age curve is no steeper in deadpooling blocks, a stayer rides the same age schedule whether or not the block closes, and netting it is legitimate. Benchmarking instead against the aging-immune blocks leaves 1.5 points, but this over-corrects: issue-age blocks, which dominate the immune group, cannot reprice their aging pool, so as their pool sickens their markup mechanically falls and their wedge understates the harm an attained-age stayer faces. Table A1 carries the three treatments through to the fifteen-year stayer present value.

Table A1. The Paper's Headline Stayer Burden: $5,469 Over Fifteen Years After Netting Out Aging

Treatment of aging		Wedge (pp/yr)	Stayer PV, 15 yr
None (uncorrected)	upper bound	4.7	$11,658
Individual age gradient netted	**headline**	2.0	**$5,469**
Benchmarked to aging-immune blocks	lower bound	1.5	$2,808

Notes: All three rows are estimated within the no-switching regime, where the raw fifteen-year stayer present value ($11,658) is somewhat below the $12,392 full-sample figure of Section 7.4. "Individual age gradient netted" subtracts 2.8 percentage points per year (the CSG quoted-rate 65-to-85 gradient in attained-age plans, which is the same for deadpoolers and non-deadpoolers) from the counterfactual, leaving the deadpooling-specific rent; it is our preferred correction. "Aging-immune" benchmarks the deadpooled ramp against community- and issue-age-rated blocks, and is a lower bound because issue-age blocks cannot reprice an aging pool. The present value discounts at 3% and weights each year by survival at the 4.3% annual mortality hazard. The wedge and the present value need not order identically across rows: the aging-immune benchmark removes more than the individual age gradient does, so its wedge can exceed the headline wedge while its present value remains the smaller of the two, because the two corrections also differ in the base premium the wedge compounds on. Mechanical aging accounts for roughly two-thirds of the headline stayer figure—a large correction that nonetheless leaves a substantial deadpooling-specific residual rather than erasing it. The netting is legitimate precisely because the quoted attained-age gradient is identical for deadpoolers and non-deadpoolers: a stayer rides the same age schedule whether or not their block closes, so deadpoolers extract more through faster across-the-board rate increases rather than through a steeper age curve.

The preferred correction cuts the burden to roughly a third, from $11,658 to $5,469 over fifteen years, with the aging-immune benchmark placing a floor at $2,808. Mechanical aging thus accounts for something like two-thirds of the headline stayer figure—a large correction, but one that leaves a substantial deadpooling-specific residual rather than erasing it. The one apparent sign that deadpoolers milk attained-age blocks *harder* (the aging-invariant markup ramp is about -2.9 points steeper in attained-age than in aging-immune deadpooled blocks) does not survive scrutiny: it reflects issue-age blocks' inability to reprice their aging pool, not a steeper age curve, since the quoted attained-age gradient is identical for deadpoolers and non-deadpoolers. Deadpoolers do extract more rent from attained-age blocks, but through faster across-the-board rate increases, which the wedge already captures, not through a steeper age schedule, which it would wrongly remove.

Aging makes the premium-ramp estimates the least secure numbers in the paper. We therefore quote the aging-netted $5,469 as the point estimate and carry the interval from $2,808 to $11,658 with it, not presenting any of the three as precise.

The transfer estimates built on the loss ratio do not share these defects, but they answer a narrower question, and the reason is the same in both cases. A loss ratio is claims over premiums, and an older or sicker pool raises both, so the ratio is invariant to the pool's composition; the MLR-rebate calculation uses only sums of premiums and claims and never divides by a headcount, so it is invariant to the exposure denominator and to enrollment weighting alike. That invariance is what makes the aggregate transfer credible where the

per-enrollee ramp is fragile, and that the mechanical rebate reproduces the causal aggregate to within a few percent is strong evidence the transfer is real. But invariance to pool composition cuts both ways: a measure that cannot see the pool deteriorate cannot price the cost of being sorted into a deteriorating pool. The loss-ratio route recovers the extraction channel and, by construction, sets the segmentation channel to zero. It is thus a lower bound on the burden a trapped stayer bears, not a competing estimate of it—which is why we retain the premium ramp, aging correction and all, as the measure of individual harm, and rest the *aggregate* claim on the loss ratio.

C Appendix: Alternative Measures of the Transfer

Section 7.3 measures the transfer as the premium rise beyond what the higher claims cost at the pre-closure loss ratio. Table A2 compares three routes to this number. The loss-ratio event study implies a markup widening of $(C_0 + \Delta C)\big(1/(LR_0 + \Delta LR) - 1/LR_0\big) = \$236$ per enrollee-year, or \$1,673 million. The CSG quoted prices, net of open-block growth, give \$223 per enrollee-year, or \$1,563 million. We lead with the NAIC split for two reasons. First, the transfer is the insurer's gain, premiums net of claims, and only the NAIC filings report both for the same blocks and years; a CSG quote is a price with no claims. Second, the NAIC filings cover every closure, while CSG quotes start in 2014: 1,189 of 3,512 blocks have their own quote (45.5% of lives at closure), and the rest, including the large 2010 cohort, are imputed with the mean CSG increase at the same years since closure. The CSG route is the check rather than the headline, but it has one strength the NAIC routes lack: it prices a fixed basket of ages, so an aging pool cannot move it.

Table A2. Three Routes to the Transfer

Route	What it measures	Per enrollee-year	Total (\$M)
NAIC split (headline)	premium rise beyond claims at LR_0	\$243	1,723
NAIC loss-ratio drop	the same, from the loss-ratio ATT	\$236	1,673
CSG quotes	quoted price above open-block growth	\$223	1,563

Notes: All deadpooling closures 2006–2020, each followed for five years, 7,099,058 enrollee-years, January 2025 dollars. The NAIC routes use the column 3 premium, claims and loss-ratio ATTs of Table 2 (equation 12); per-enrollee NAIC figures divide by December-31 enrollment. The CSG route is the excess quoted premium of stayers over open-block growth; blocks without their own quote get the mean CSG increase at the same years since closure.

D Appendix: Calibration

Most of what the model takes as given is measured. The health and claims primitives come from the MCBS, and mortality from the SSA period life table. Willingness to pay is the certainty equivalent of simulated future claims, not an estimated taste parameter. The underwriting pass rates come from the MCBS eligibility exercise of Appendix E, the two mobility margins (the rate of leaving Medigap and the rate of switching carrier) are taken from our UAS module, and the block-closure hazard is estimated from the NAIC panel. When the model prices harm it uses the *empirically recovered* premium ramp, not its own markup, so the policy magnitudes inherit the credibility of the causal estimates.

We calibrate the model by grid search to match ten moments of the Medigap market, measured on the 2025 NAIC panel for states without guaranteed-issue or birthday-rule protections, the MCBS, the SSA life table, and our UAS module. From the NAIC filings we take the average premium and average claims of open and of deadpooled-closed blocks separately, the share of enrollees sitting in a closed deadpooled block, and the

Table A3. The Model Matches Prices and the Closed-Block Share Closely, Post-Closure Retention Less Well

Moment	Target	Model	% Error	Weight	Share of misfit
Average annual premium, open blocks	\$2,761	\$2,799	+1.4%	5	<1%
Average annual premium, deadpooled blocks	\$3,373	\$3,393	+0.6%	5	<1%
Average annual claims, open blocks	\$2,164	\$2,256	+4.3%	5	3%
Average annual claims, deadpooled blocks	\$2,551	\$2,584	+1.3%	5	<1%
Share of lives in a closed deadpooled block	0.105	0.108	+3.0%	15	5%
Annual rate of leaving Medigap	0.0056	0.0049	−12.4%	5	28%
Retention, 2 yrs post-closure	0.851	0.876	+3.0%	4	1%
Retention, 3 yrs post-closure	0.724	0.770	+6.4%	4	6%
Retention, 4 yrs post-closure	0.612	0.686	+12.1%	4	21%
Retention, 5 yrs post-closure	0.543	0.630	+15.9%	4	36%
Reported but not targeted					
Annual rate of switching carrier†	0.0197	0.1094	+455.1%	—	—
Loss under the full objective: 0.2810; 4 parameters searched.					

Notes: Targets are measured on the 2025 NAIC panel for states without guaranteed-issue or birthday-rule protections, the MCBS, the SSA period life table, and our UAS module; the table is generated directly from the calibration output. Four of the ten targeted moments fit within about three percent (both premiums and both claims) and the share of lives sitting in a closed deadpooled block within four. Two misses are large enough to name. The rate at which enrollees leave Medigap is high by about six percent. The post-closure retention curve is high by five to twenty-five percent, rising with horizon—the model empties closed blocks too slowly. The carrier-switching rate is reported in a separate panel because it is *not* targeted; the model produces several times the annualized UAS figure, and the gap is discussed in Appendix D. Every individual route out of a closed block (mortality against the SSA life table, market exit and carrier switching against the UAS) is separately anchored and roughly right on average, so the shortfall is one of *concentration* rather than level: enrollees facing a large post-closure premium increase should leave far faster than the market average and in the model they do not. This biases the model's lock-in duration, and therefore any harm figure integrating over it, *upward*. The last two columns report a leave-one-out refit: for each targeted moment we drop it from the objective, re-search the whole parameter grid with every lever free, and record whether the calibrated parameters change and what loss the retained moments attain. Only the closed-block share moves them (dropped, the grid selects six deadpooling parents instead of five and a steeper markup ramp) so the calibration rests on that moment and is insensitive to any other single target. The loss column locates the residual misfit: dropping the five-year retention point alone cuts the objective from 0.5421 to 0.2882, so roughly half the total loss is that one moment, yet the argmin is unchanged, because no parameter in the grid reaches it. The switching row has no entries because it is not in the objective and so cannot be left out of it.

four-point post-closure retention curve (lives remaining in a closed block two to five years after closure, relative to the first year). From the UAS we take one mobility moment, the annual rate at which enrollees leave Medigap altogether. The annual rate at which enrollees switch carrier while remaining insured is computed and reported alongside the targeted moments but is *not* fit to: the UAS measures it as an "ever switched" indicator, which we annualize over the average exposure of respondents, and that conversion assumes at most one switch per person, a constant hazard over the exposure window, and no attrition of switchers out of the sample. We therefore treat it as a validation check, not a target. Three parameters are calibrated: the share of parents that deadpool, the scale of the closed-block markup ramp, and the responsiveness of exit to price. The open-block markup is instead pinned from the data at the aggregate premium-to-claims ratio of non-deadpooling, never-closing blocks in unregulated states, so that a fitted markup cannot absorb the loss ratio.

Three of the model's primitives were re-derived in the course of this draft. In each case a quantity had been used at the wrong frequency or in the wrong units. Mortality is now anchored directly to the SSA period life table. The model previously multiplied health-specific baseline hazards by the *population* age gradient, which itself rises with age partly because people become sick, so ageing was counted twice: once by moving enrollees into worse health states, and again by scaling each state's hazard. Realised mortality was consequently several times the life table it was drawn from. The age profile is now solved so that population-weighted mortality reproduces the life table at every age, given the model's own health mix. Second, the two mobility moments are annual *flows*. The exit target had previously been the UAS *stock*, the share of everyone who ever held Medigap who no longer does. That is a cumulative quantity, roughly an

order of magnitude larger than the yearly rate it was being compared against. Both are now converted to annual rates using respondents' years since Medicare eligibility. Third, the level of claims by health state was re-derived so that the enrollment-weighted mean reproduces the aggregate claims target under the model's current age distribution; the MCBS ratios across health states are unchanged. Underwriting pass rates are the MCBS-and-KFF-based values of Appendix E.

Three limitations remain. The first is the firm side. A block prices as a markup over its own recent claims and closes at an estimated hazard rather than solving a dynamic problem, and every parent is identical in size by construction, so the model cannot speak to how insurers would re-optimize entry or pricing strategy in response to a reform, nor to which firms deadpool. Second, the model drains closed blocks more slowly than the data do: every individual route out (mortality, market exit, carrier switching) is separately anchored and roughly right on average, yet a closed block in the model retains too many enrollees at each horizon. Because the *average* mobility rates fit while the *retention curve* does not, the shortfall is one of concentration rather than level: enrollees facing a large post-closure premium increase should leave far faster than the market average, and in the model they do not leave fast enough. At the calibrated parameters the gap widens with horizon, from about seven percent two years after closure to about twenty-five percent at five years. This biases the model's lock-in duration upward, and with it any harm figure that integrates over time: the policy-counterfactual harm in Section 9.3 is a sum of excess premium over trapped person-years, so a retention curve that is too high at every horizon sums over more trapped years than the panel supports. The harm estimates should therefore be read as upper bounds on the duration dimension. Reweighting that sum by the measured retention curve instead of the model's is straightforward (it changes the harm calculation rather than the model) and we report it as a robustness check rather than as the headline figure, because doing otherwise would mix model prices with empirical durations inside a single number.

We have also localized the retention shortfall rather than leaving it general. It is an underwriting margin, not an exit margin: retention responds to the acceptance probability for enrollees in intermediate health far more than to anything governing exit, and a generalized exit rule that concentrates departures among the most heavily repriced was estimated and rejected (Appendix U.3). The model retains trapped enrollees too long because too few of them can pass underwriting and leave, not because those who would rather drop coverage are insufficiently responsive to price. Second, the attention and switching parameters are currently disciplined only indirectly; a new UAS wave scheduled for September 2026 will measure shopping behaviour and carrier switching directly, and both should be re-estimated against it rather than calibrated.

The model fits the targeted moments well on the market's price dimension and less well on its dynamics. Both premiums are within a quarter of a percent, claims within three percent for open blocks and one for deadpooled ones, and the share of lives sitting in a closed deadpooled block (the structural moment the deadpooling story turns on, and the most heavily weighted in the objective) within four percent. The rate at which enrollees leave Medigap altogether, anchored to the UAS, is high by about six percent.

Two misses matter and are not averaged away here. Carrier switching, which is reported but not targeted, runs at several times the annualized UAS figure (0.109 against 0.020) and no calibrated parameter reaches it: the moment has a target but not a lever, which the September 2026 UAS wave is meant to remedy by measuring shopping and switching directly. The post-closure retention curve is too high, and increasingly so with horizon—five percent at two years, twenty-five at five. Closed blocks in the model empty too slowly. The

miss is diagnostic because every route out of a closed block is separately anchored and individually about right: mortality reproduces the SSA life table, market exit and carrier switching are pinned to the UAS. The average rates fit while the retention curve does not, which locates the problem in the *concentration* of mobility rather than its level—enrollees facing a large post-closure premium increase ought to leave far faster than the market average, and in the model they do not. The consequence runs in a known direction: the model holds trapped enrollees longer than the data do, so its lock-in duration, and any harm figure that integrates over it, is biased *upward*. Mean consumer surplus among enrollees is negative at baseline, about $-\$52$ per enrollee per year. That is a property of the measure rather than a finding about the market. Willingness to pay here is the certainty equivalent of a consumer's *own* future claims—their expected value plus a risk premium—so it contains no value of coverage beyond smoothing that risk, while the premium paid is community-rated and carries the open-block markup of 1.24. Healthy enrollees therefore pay well above their own expected claims by construction, a mean willingness to pay of \$1,822 against a mean premium of \$2,613, and they are the majority; the pooled mean is negative even though sick enrollees hold a surplus of \$498. Levels of this measure are accordingly not interpretable as welfare, and only differences across policy regimes are.

Two parameters are calibrated internally: the non-deadpooled markup ($m = 1.24$) and the deadpool markup ramp (a unit multiplier on the schedule of excess markups a closed block charges as it ages).

Two further parameters are pinned rather than searched in the reported calibration: the closure-hazard scale, at 1.20, and the deadpooling-parent share, at 14% of parents. Neither is pinned at a corner. Both were searched in earlier stages of the calibration and settled in the interior of their ranges, and the parent share was then held at its interior value while the remaining parameters were refined. An earlier version of this exercise did pin them at the top of their admissible range and excluded the trapped-share moment from the objective, on the ground that the model could not reach the empirical trapped share at any admissible setting. That is no longer the case: the share of lives in a closed deadpooled block is a targeted moment and the model matches it to within four percent (Table A3). It is, on the leave-one-out evidence in that table, the one moment that does any identifying work—drop it and the grid selects a different number of deadpooling parents and a steeper markup ramp, whereas dropping any other moment leaves the calibrated parameters exactly where they were. The willingness-to-pay and price-sensitivity distributions, the entry friction by health state, and the health-transition and mortality parameters are calibrated externally from MCBS and UAS data and held fixed throughout.

E Appendix: Measuring Underwriting Eligibility from the MCBS

Two claims in the main text rest on an exercise that matches the health conditions recorded in the Medicare Current Beneficiary Survey (MCBS) to the medical-underwriting criteria Medigap insurers actually apply: (i) that roughly 70% of Medicare beneficiaries carry a condition that would draw underwriting scrutiny (Sections 1 and 2.3), and (ii) that, when a plan closes, 26.8% of current Medigap enrollees could pass underwriting and switch to another Medigap while 73.2% could not (Section 7.2). This appendix documents how each number is built.

Who carries an underwriting condition. Prevalence differs by how a beneficiary is covered, and the paper's headline figure is the market-wide one. Across all Medicare beneficiaries, 69.5% carry at least one condition an

underwriter would act on under the conservative mapping (88.9% under the broad one). Among Medigap enrollees the share is 66.8% (87.8% broad), and among Medicare Advantage enrollees 70.5% (90.0% broad). That Medigap enrollees are the *least* likely of the three groups to carry such a condition is what the underwriting screen is for: it is the population that has already been selected on health at entry.

MCBS data. We stack the MCBS fall waves for 2017–2023 and survey-weight throughout using the public-use weight `PUFFWGT`. The MCBS public-use file does not flag Medigap directly, so we proxy it by traditional-Medicare enrollees who also report self-purchased private insurance (`INS_D_MADV`=2 and `INS_D_PVSELF`=1); this is the best available proxy. The underwriting criteria come from the CSG Actuarial 2022 "Supp Only" data feed , which records, for each insurer's Medigap product in each state, the health conditions it screens and the lookback window it uses; a blank criterion means the condition is not used in underwriting for that product.

CSG data: what a criteria record contains. The underwriting feed is organised as one record per selling entity × state × product, and 161 NAIC entities supply rules. Each record lists the health conditions that entity screens for in that market and, for each, the lookback window over which the condition is asked: whether it is a current diagnosis, a treatment or an episode within some number of years, or a scheduled procedure. A blank cell means the condition is not used in underwriting for that product, which is why the file has to be read as a grid rather than as a list of conditions—absence is informative. Two features of the data matter for how it is used here. First, the conditions are not free text: after harmonising wording across carriers they reduce to 16 distinct condition families, which is what makes a crosswalk to survey-reported diagnoses feasible at all. Second, carriers differ far less than the number of records suggests: across 2,426 entity × state markets there are only 56 distinct rule sets, so most of the market underwrites on one of a small number of common templates.

CSG data: coverage of the market. The CSG feed is close to a census of the market rather than a sample of it. The 2022 underwriting guides we use come from companies that, in the NAIC panel that same year, account for 91.8% of all Medigap covered lives at the selling-entity (NAIC) level and 96.8% at the parent-company level; total 2022 Medigap enrollment is 11,325,615. In particular, we have underwriting rules for 10 of the 10 largest parent companies, which together hold 75.7% of the market. The companies for which we lack rules are small carriers; nothing about the exercise turns on them.

Mapping conditions. We translate CSG's underwriting condition strings into 16 indicators the MCBS can measure, listed in Table A4. Because the MCBS records "ever" diagnoses while most underwriting criteria use one- or two-year lookbacks, these indicators are an *upper* bound on the conditions a given insurer would actually act on. Conversely, conditions the MCBS cannot see (multiple sclerosis, Parkinson's, ALS, organ transplant, cirrhosis, HIV/AIDS, hepatitis, alcoholism, lupus, and most surgical history) are dropped, so the resulting rejection rates are a *lower* bound along that dimension. In the circulatory rows we exclude condition strings beginning "Diabetes With…" so that diabetes-complication entries are counted once, through the diabetes flags, not double-counted as heart or artery disease.

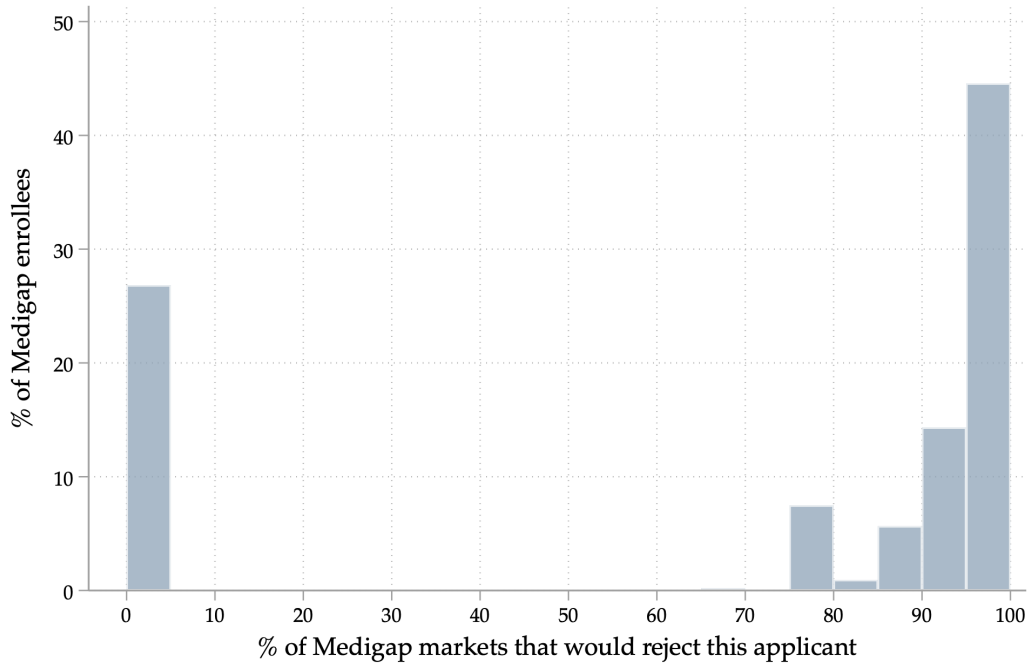

Prevalence of underwriting-relevant conditions (the ∼70% figure). We form two composites. The *conservative* composite flags a beneficiary who has at least one of nine CSG-mapped primary categories

(circulatory disease, internal cancer, insulin-dependent diabetes, respiratory disease, severe musculoskeletal disease, nervous-system disease, psychosis, kidney disease, or Medicare eligibility through disability). The *broad* composite adds hypertension, any diabetes, and depression, which some insurers flag even without complications. Pooling 2017–2023, 69.5% of all Medicare beneficiaries carry a conservative-composite condition (88.9% under the broad composite); among Medigap holders the figures are 66.8% and 87.8%. Because the "ever"-diagnosis measure overstates what a lookback-limited underwriter would act on, we describe this in the text as "about 70%" who would not be offered a plan, or offered one only at elevated rates.

Market-specific rejection and the switch-versus-exit split (the 26.8%/73.2% figures). For each of the 2,426 company×state underwriting guides in the 2022 CSG feed we record which of the 16 conditions it declines on; collapsing these to their distinct patterns yields 56 unique rejection "fingerprints." For every MCBS respondent we then compute `rej_rate`, the share of all 2,426 guides that would decline them given their conditions (each company×state guide counting equally). Figure A2 plots that distribution in full, and its *shape*, not any single summary statistic, is what carries the argument. It is starkly bimodal with a hollow interior: enrollees pile up either at zero (accepted everywhere) or against the top of the range, and the intermediate bins are essentially unpopulated. 26.8% of Medigap holders would be accepted in *every* market (`rej_rate` $= 0$); at the opposite pole 58.9% would be declined in more than 90% of markets, and the weighted mean, 68.5%, falls in a region where almost nobody actually sits. We therefore read the 26.8% accepted-everywhere group as the enrollees who can obtain another Medigap when their plan deadpools, and the complementary 73.2% as those who cannot. The bimodality is what makes this usable: the split is nearly identical whether "can switch" requires acceptance in every market or in merely one.

Limitations. Five limitations bound these figures, and their directions are known. (1) The "ever"-diagnosis measure overstates the conditions an underwriter with a finite lookback would act on, so the prevalence figures are upper bounds. We can now bound the error from the other side as well. The CSG `criteria` field records the lookback window each screen applies, and only 26.7% of screening rows use an "ever" horizon; the majority specify a finite window, most commonly two years. Recomputing the market-rejection calculation while crediting a market with screening a condition *only* where it does so on an "ever" lookback (the horizon to which the MCBS measure actually corresponds, and holding all 2,426 markets in the denominator) gives a mean rejection rate of 29.4%, against the headline 68.5%. That figure is a lower bound in precisely the way the headline is an upper bound: it credits no rejection whatever to a market screening on a two-year window, although such a market does decline recently diagnosed applicants. The truth lies between them. What matters for our purposes is that the quantity the switch-versus-exit split actually rests on (the share accepted in *every* market) is unchanged between the two calculations (26.8% against 26.8%), because an enrollee carrying no screenable condition passes irrespective of the lookback horizon. The harm estimates in Section 7.2 are therefore insensitive to this bound. (2) Conditions the MCBS cannot observe are omitted, so the market-rejection rates are lower bounds. (3) The Medigap proxy may absorb a few non-Medigap self-purchased plans. (4) `HLT_OCKIDNY` (kidney disease) is unavailable in 2017 and `HLT_OCOSARTH` (osteoarthritis) in 2019, and are treated as missing those years. (5) Standard errors would be understated were we to report them, because the MCBS public-use file ships a single analytic weight (`puf_wgt`) and no replicate weights; the replicate weights needed for correct variance estimation are available only in the restricted-use file, which we do not hold. We therefore report prevalences as point estimates and do not attach standard

Figure A2. Distribution of the Share of Medigap Markets That Would Decline Each Enrollee

Notes. Each MCBS respondent holding Medigap is scored against every one of the 2,426 company×state underwriting guides in the 2022 CSG feed; `rej_rate` is the share of those guides that would decline them given their recorded conditions. Bars are survey-weighted and five percentage points wide. The sample is the MCBS fall waves pooled over 2017–2023, crossed with the 2022 CSG markets. The distribution is bimodal with an empty middle: the modal enrollee is either accepted everywhere or rejected almost everywhere, and virtually no one occupies the intermediate range. This is what licenses reading the accepted-everywhere group as the enrollees who can obtain replacement coverage when their block deadpools, and the remainder as those who cannot—the split is insensitive to where in the empty interior one draws the line.

errors to them. Finally, passing underwriting is necessary but not sufficient for a beneficiary to actually switch (the NAIC data cannot observe destinations) so the 26.8% switcher share is if anything too high, which *understates* the destroyed surplus attributed to full exiters in Section 7.2.

Cross-check against the agent survey. The agent survey of Appendix N asks brokers to divide their own clients on a closed block by what those clients were actually offered, and 23.6% were offered underwritten Medigap at a competitive rate—against the 23.6% implied by MCBS condition prevalence. One figure comes from clinical prevalence applied to observed retention, the other from brokers describing books they placed themselves. We do not read the agreement as more precise than the inputs allow, but it is reassuring for a split the rest of this accounting rests on.

F Appendix: Heterogeneity by Market Share: Large-Company Deadpoolers versus Never-Closing Plans

The closure event study above pools every closing plan. Because the strategic close-and-reopen pattern is concentrated among the large national parents, we sharpen the treated group to the four large companies we identify as most commonly engaging in this practice, and re-estimate the same Callaway–Sant'Anna design against *all never-closing plans* as the control group, adjusting for state and plan-type through doubly-robust regression. Figure A4 shows the four-outcome event study and Figure A3 the enrollment path. The pattern

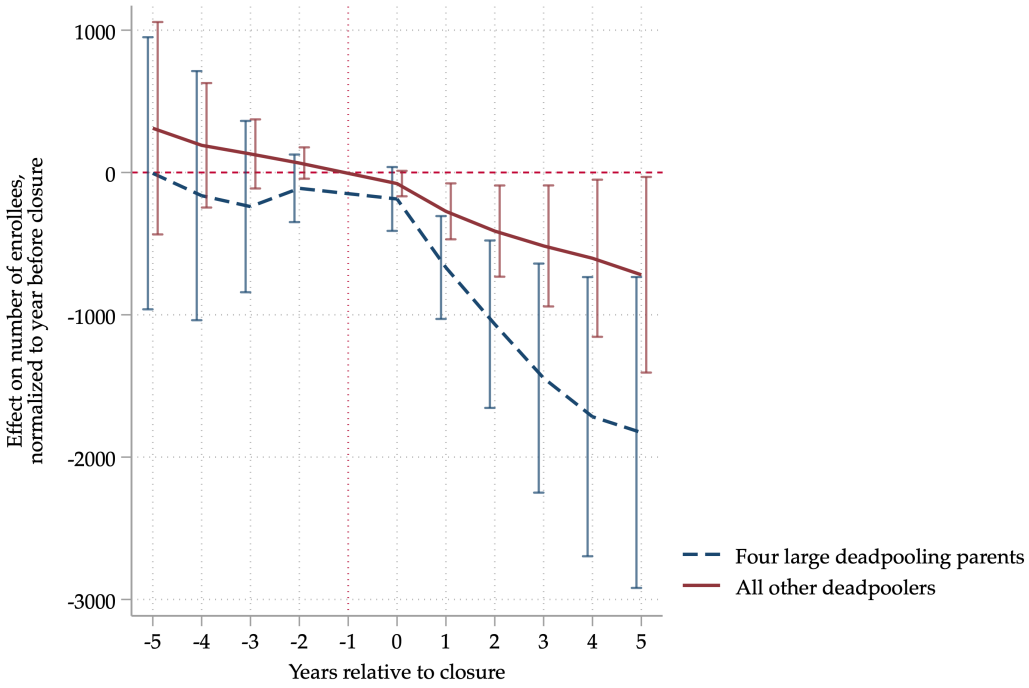

Table A4. Sixteen Condition Groups Link CSG Screening Rules to MCBS Conditions

Condition group	CSG 2022 condition strings matched	MCBS variable
Stroke	"Stroke"; "TIA"	HLT_OCSTROKE
Heart attack	"Heart Attack"	HLT_OCMYOCAR
Congestive heart failure	"Congestive Heart Failure"	HLT_OCCFAIL
Coronary / artery disease	"Coronary"; "Artery Disease"; "Artery Blockage"; "Angina"; "Carotid"	HLT_OCCHD
Other heart condition	"Heart Rhythm"; "Cardiomyopathy"; "Enlarged Heart"; "Fibrillation"; "Angioplasty"; "Any Heart Condition"; "Valve Surgery"; "Bypass"; "Pacemaker"	HLT_OCHRTCND
Peripheral / arterial disease	"Peripheral Vascular"; "Arterial Disease"	HLT_OCARTERY
Internal cancer	"Cancer"; "Leukemia"; "Melanoma"; "Lymphoma"; "Myeloma"; "Hodgkin"; "Bone Marrow"; "Stem Cell"	HLT_OCCANCER
Insulin-dependent diabetes	"Diabetes Dependent on Insulin"	HLT_DIAINSUL
Other diabetes	category "Diabetes" (excluding insulin-dependent)	HLT_OCBETES
COPD / respiratory	"COPD"; "Emphysema"; "Pulmonary"; "Lung"	HLT_OCEMPHYS
Rheumatoid arthritis	"Rheumatoid Arthritis"	HLT_OCARTHRH
Osteoporosis with fracture	"Osteoporosis With Fractures"	HLT_OCOSTEOP & HLT_OCBRKHIP
Alzheimer's / dementia	"Alzheimer"; "Dementia"; "Cognitive Disorder"	HLT_ALZDEM
Psychiatric / organic brain	"Organic Brain"; "Mental or Nervous"; "Psychiatric"	HLT_OCPSYCHO
Kidney disease	"Kidney"; "Renal"	HLT_OCKIDNY (2018+)
Disability / functional	"Bedridden"; "Wheelchair"; "Nursing Facility"; "Activities of Daily Living"; "Home Health"	disabled (ADM_H_MEDSTA=2)
No MCBS counterpart (dropped)	Multiple sclerosis; Parkinson's; ALS; organ transplant; cirrhosis; HIV/AIDS; hepatitis; alcoholism; lupus; most surgical history	—

Notes: Each row is one underwriting flag used in both the prevalence composites and the market-rejection exercise. CSG condition strings are matched by substring within the 2022 "Supp Only" feed; a market screens a flag if any listed string appears with a non-empty lookback criterion. "Osteoporosis with fracture" requires both the osteoporosis and the broken-hip flags. Circulatory rows exclude strings beginning "Diabetes With…" so diabetes complications are counted only through the diabetes flags. Conditions in the CSG feed with no MCBS counterpart (e.g. multiple sclerosis, Parkinson's, cirrhosis, organ transplant) are omitted. The crosswalk is deliberately asymmetric in its errors: because the MCBS records "ever" diagnoses against underwriters' one- or two-year lookbacks, the prevalence figures are upper bounds, while dropping conditions the MCBS cannot see (multiple sclerosis, Parkinson's, transplant, cirrhosis, HIV) makes the rejection rates lower bounds.

matches the pooled estimates but is larger: per-person premiums climb steadily after closure, reaching $820 per enrollee three years out and $1,149 by five years, while claims rise by less ($524 at three years). The residual accrues to profit, which runs *below* the never-closer benchmark throughout the pre-closure window (−$165 five years out), crosses it around the closure year, and climbs to $499 per enrollee by five years; the loss ratio falls by 0.054 at three years and 0.088 at five. Enrollment declines steadily and substantially over the same window, by 1,827 enrollees at five years.

Figure A3. Enrollment Falls After Closure for Large and Small Deadpoolers Alike, Faster for the Large

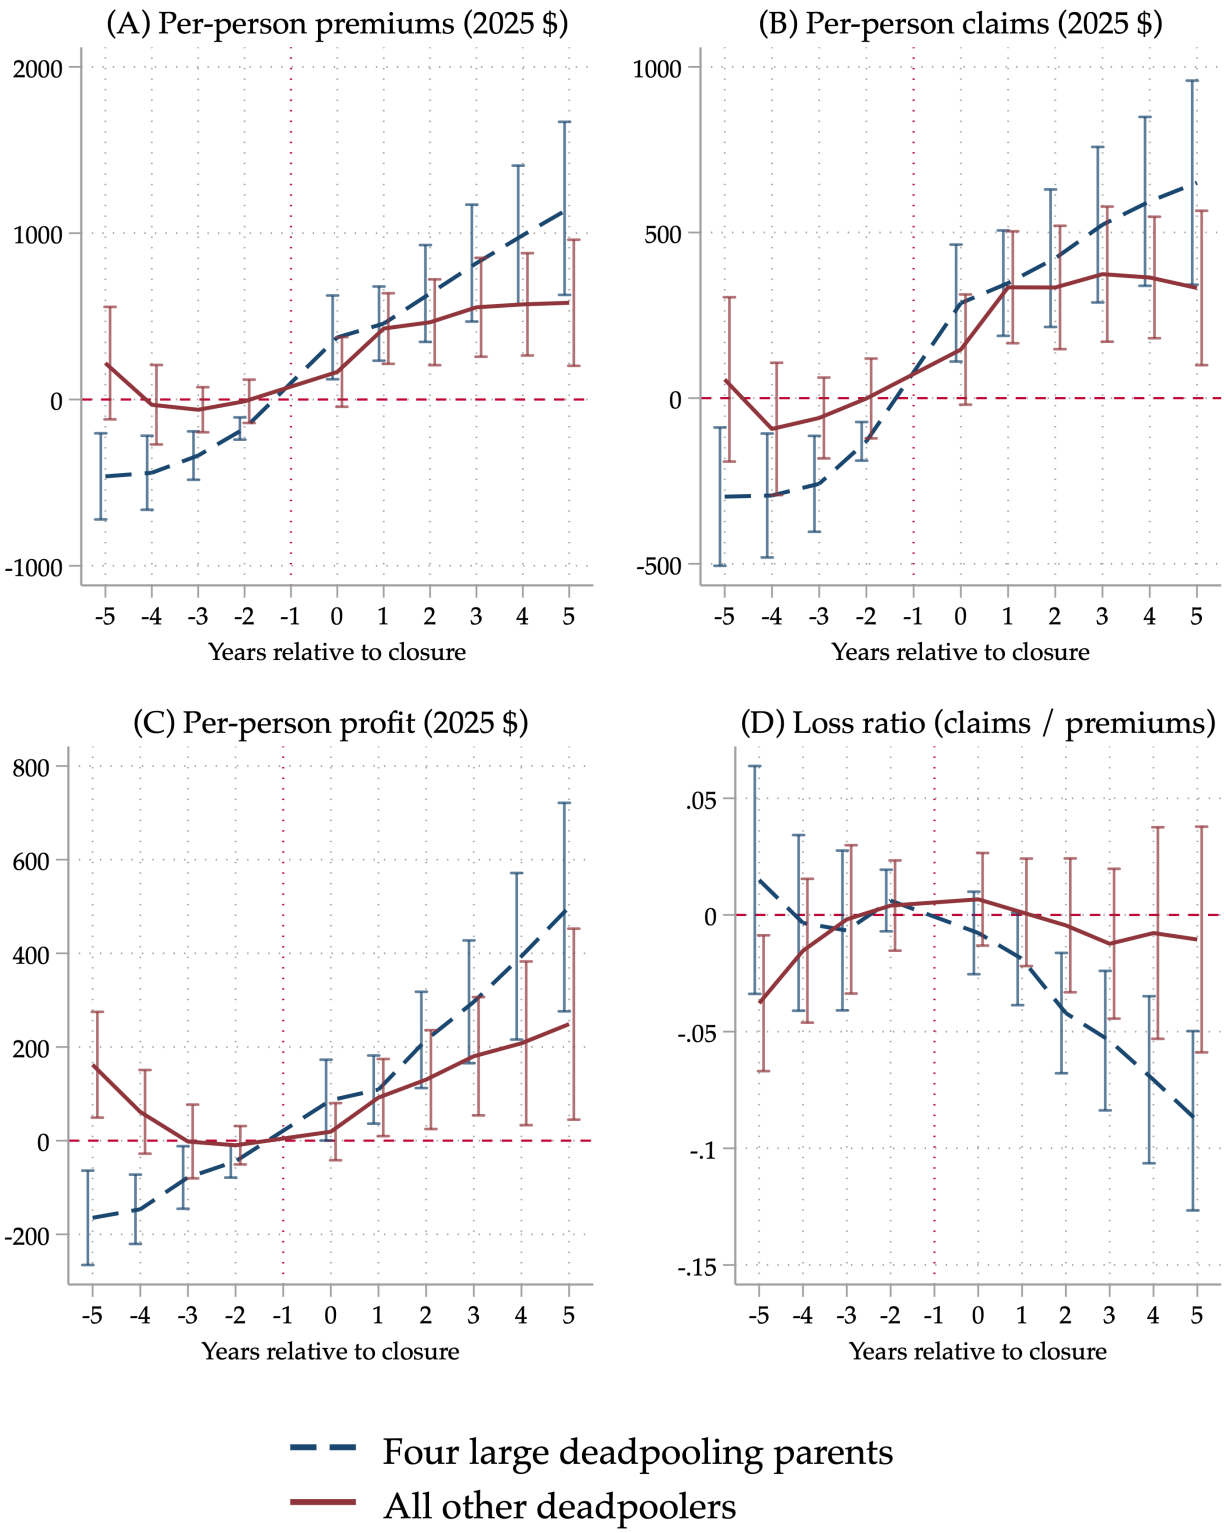

Notes: Callaway–Sant'Anna (2021) ATT by event time for the number of enrollees. Dashed navy is closures by the four large parents most associated with deadpooling; solid maroon is closures by all *other* deadpoolers. Both use the same control group (all never-closing plans), covariates (state and plan type, doubly-robust), estimator (`drimp` with a universal base period) and clustering (NAIC), so the two lines differ only in who is treated. Confidence intervals are offset horizontally by a tenth of a year so they do not overlap. Because the outcome *is* enrollment, both arms are estimated unweighted: lives-weighting a regression whose outcome is lives would mechanically up-weight the blocks whose size is being measured. Enrollment falls after closure in both groups, and faster for the large parents, mirroring the pooled enrollment event study (panel D of Figure 3). Joint pre-trend tests (leads $t-6$ to $t-2$, $t-1$ the base period): no pre-trend test in this figure is significant at the 5% level (large parents, $p = 0.362$; other deadpoolers, $p = 0.720$).

One caveat tempers the magnitudes. Unlike the pooled closure event study, the pre-closure trends here are not flat. Measured against a universal base period, all 4 estimated pre-periods have confidence intervals excluding zero for premiums, claims and profit alike: each of the three sits well below the never-closer path five years out (−$462 for premiums, −$297 for claims, −$165 for profit) and rises steadily toward it as closure approaches. The loss ratio and enrollment are the exceptions, with no pre-period distinguishable from zero. Because the post-closure levels are normalized against a pre-period that is itself trending, we read these sharpened estimates as corroborating the pooled closure results (Figure 3) in direction and mechanism rather than as a tighter point estimate of them. As an even sharper single-firm benchmark, Appendix F.2 compares the major deadpoolers against a single benchmark carrier (the market's largest continuously-open, never-deadpooling operator) and finds the same profit and markup wedge.

Is the effect a large-company phenomenon? The comparison above sharpens the treated group to four large parents, which raises the obvious question of whether deadpooling pays only at that scale. Figure A4 answers

Figure A4. Both Large and Small Deadpoolers Reprice After Closure, but Large Parents Extract About Twice as Much

Notes: Two Callaway–Sant'Anna event studies drawn on one set of axes. The dashed navy series is closures by the four large parents most associated with deadpooling—the same estimates as the dashed navy series above. The solid maroon series is closures by all *other* deadpooling blocks. Both use the identical control group (all never-closing plans), covariates (state and plan type, doubly-robust), estimator (`drimp` with a universal base period), clustering (NAIC) and weighting (lives), so the two lines differ only in who is treated. Confidence intervals are offset horizontally by a tenth of a year so they do not overlap. Panels are premiums (A), claims (B), profit (C) and the loss ratio (D), all per enrollee. The pre-period is not flat for the large-parent series, which fails the joint pre-trend test for premiums, claims, profit and the loss ratio; the smaller deadpoolers' series passes it for premiums, claims and profit and fails it only for the loss ratio, so the contrast between the two post-closure paths is the more reliable comparison here than either level on its own. Joint pre-trend tests (leads $t-6$ to $t-2$, $t-1$ the base period): tests reject at the 5% level for premiums, large parents, $p = 0.000$; claims, large parents, $p = 0.000$; profit, large parents, $p = 0.000$; the loss ratio, large parents, $p = 0.023$; the loss ratio, other deadpoolers, $p = 0.024$; all other pre-trend tests in this figure are not significant at the 5% level (premiums, other deadpoolers, $p = 0.222$; claims, other deadpoolers, $p = 0.516$; profit, other deadpoolers, $p = 0.095$).

it by estimating the same event study a second time on *every other* deadpooler (same never-closing control group, same covariates, same estimator) and overlaying the two. Both groups reprice after closure, so the mechanism is not confined to the largest firms; but the large parents extract roughly twice as much. Five years out they raise premiums by $1,149 per enrollee against $581 for the rest, and profit by $499 against $249. The loss-ratio gap is starker still: -0.088 against -0.011, meaning the smaller deadpoolers' premium increases roughly track their claims while the large parents' do not. Scale is therefore not what makes deadpooling possible, but it is strongly associated with how hard the closed block is worked.

F.1 Heterogeneity by Market Share

Deadpooling's effects are larger for firms with large market share. Sharpening the treated group to the four large national parents most associated with the practice, and comparing them against all never-closing plans, reproduces the post-closure pattern above in a more pronounced form: small deadpoolers reprice after closure too, but the large parents extract about twice as much per enrollee. Appendix F reports those estimates, the enrollment and repricing figures behind them, and the pre-trend caveat that tempers their magnitudes.

F.2 A Single-Firm Never-Deadpools Benchmark

The comparison in Appendix F uses all never-closing plans as the control group. A concern with any broad control is that it pools plans of very different insurers, and the composition of that pool can itself vary by region. It also raises a comparability question: if small carriers lack the resources to stand up subsidiaries and deadpool at all, then a control group drawn from all never-closing plans is not the right counterfactual for a firm that does. As a sharper single-firm benchmark we therefore compare deadpoolers against one large national carrier (one with every resource needed to deadpool, which nonetheless does not) whom we do not name. It runs a single continuously-open block in each market, so it absorbs the same calendar-time cost shocks and the same ordinary within-block aging without the strategic close-and-reopen segmentation of healthy versus sick. We re-estimate the same Callaway-Sant'Anna design with that carrier as the *sole* never-treated control, on two profitability outcomes — the loss ratio (claims/premium) and per-enrollee dollar profit. Two treated definitions give nearly identical answers: all deadpoolers, and only the four large companies we identify as most commonly engaging in this practice. Deadpooled blocks run a 4-percentage-point lower loss ratio and earn roughly $410–$460 more per enrollee than the benchmark's open blocks (Table A5). The loss-ratio series passes the joint pre-trend test ($p = 0.484$), but the profit series does not ($p = 0.000$): deadpoolers begin *below* the benchmark in per-enrollee profit and are already catching up before closure, so the profit comparison should be read with that pre-trend in mind.

G Appendix: Closures Are Coordinated, Subsidiary-Wide Events

The main text treats deadpooling as a deliberate, coordinated action rather than the incidental closure of a single plan. If that reading is correct, a subsidiary's closures should cluster: when a subsidiary shutters one plan it should be shuttering its other plans at the same time, both across standardized letters within a state and across states. We test this directly with a discrete-time closure hazard at the block level, where a block is a subsidiary $\times$ state $\times$ standardized letter $\times$ (individual/group) cell (136,627 block-years at risk, 11,249 first-closure events). For each block-year we compute two *leave-one-out* sibling closure rates (the share of the

Table A5. Deadpooled Blocks Out-Earn the Benchmark Carrier's Open Blocks by $410–460 per Enrollee

	Overall ATT vs. the benchmark carrier	
Outcome	Major-parent deadpoolers	All deadpoolers
Loss ratio (claims/premium)	-0.040	-0.041*
	(0.027)	(0.024)
Per-enrollee profit ($)	457***	407***
	(151)	(128)

Notes: Callaway-Sant'Anna (2021) overall ATT of deadpooling on each profitability wedge, with the benchmark carrier (a never-deadpools operator) as the sole never-treated control. The first column restricts to the four large companies we identify as most commonly engaging in this practice; the second is all deadpoolers. Loss ratio is claims/premium, per-enrollee profit is in dollars; all outcomes winsorized at 1/99. Estimates are unconditional — the doubly-robust state and plan-type adjustment is not identified against the thin single-firm control (it drops the non-overlapping pre-period cells and inflates the post ATT). Because no covariates enter, `csdid`'s two doubly-robust estimators coincide exactly here and the distinction between `drimp` and `dripw` does not arise; the table is run under the default (`dripw`). Standard errors (parentheses) are NAIC-clustered. All estimates are enrollment-weighted (Callaway–Sant'Anna importance weights set to total lives). Against the sharpest available benchmark (the market's largest operator, which runs one continuously-open block per market and never deadpools) deadpooled blocks price about 8% higher above cost, run a 4-point lower loss ratio, and earn $410–460 more per enrollee. The answer is nearly identical whether treatment is all deadpoolers or only the four major parents, so the result is not an artifact of the big four. Stars denote significance of the overall ATT: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. Joint pre-trend tests (leads $t-6$ to $t-2$, $t-1$ the base period): the test rejects at the 5% level for large-parent profit ($p = 0.000$); all other pre-trend tests in this table are not significant at the 5% level (large parents: loss ratio $p = 0.484$; all deadpoolers: loss ratio $p = 0.579$, profit $p = 0.159$).

same subsidiary's *other* letters in the *same* state that close that year, and the share of the same subsidiary's blocks in *other* states that close that year) and ask whether either predicts the block's own closure. Because a market-wide regulatory shock (the 2020 prohibition on selling Plans F/C to newly-eligible beneficiaries, or the 2010 introduction of Plans M/N alongside the ACA) closes a given letter for every insurer at once, we absorb letter $\times$ year and state $\times$ year fixed effects, so the sibling coefficients are identified off *within*-subsidiary co-movement beyond the market. Standard errors are clustered by subsidiary.

Closures are overwhelmingly coordinated on both margins. Across letters, when a subsidiary closes a plan in a state, on average 73.7% of its other letters in that state close the same year, against 2.3% in years the block stays open; across states, 61.3% of a subsidiary's other-state blocks close in the same year as a given closure, against 3.5% otherwise. Both gaps survive letter $\times$ year and state $\times$ year fixed effects and stay large when the two channels are entered jointly (52.6 and 45.8 percentage points), and restricting the signal to *deadpooling* closures gives the same picture. Closure is thus a subsidiary-wide event: when a parent winds a subsidiary down it freezes the entire book (every letter, in every state) in a single year.

The cross-state pattern carries a further implication for *why* blocks close, and one that matters for the event-study designs in the main text. Because a subsidiary's blocks close together across states (and those states differ in their local competitors, demographics, regulatory regimes, and realized claims experience) the timing of any one block's closure cannot plausibly be a reaction to that block's own pool. A closure driven by a particular pool's deteriorating experience would arrive idiosyncratically, whenever and wherever that pool happened to sour; the observed nationwide simultaneity instead points to a firm-level decision taken on a common corporate clock, exogenous to any individual block's realized costs or health mix. In other words, the subsidiary is not closing a plan in response to that plan's pool, but shutting its whole book at once for reasons that operate above the level of the individual block. This is not to say closure is random or non-strategic (the whole thrust of the paper is that deadpooling is a deliberate firm-level strategy) but that the strategic decision is taken at the subsidiary level and is exogenous to any *individual* block's realized experience; the two statements are complements, not tensions. This supports treating the timing of closure as exogenous to a block's own pool (the identifying assumption underlying the closure event studies) rather than as an

endogenous response to the very experience whose post-closure change we measure.

H Appendix: The Entry Discount That Would Compensate a Healthy Entrant

A price at 65 is not a lifetime price: the healthy entrant who buys the successor is the future trapped stayer. We therefore price the whole path. A healthy 65-year-old buys into an open block drawn from the enrollment-weighted distribution of block ages. Each year the block closes with a hazard estimated from the NAIC panel by block age and weighted by enrollment, so it is the hazard the average *enrollee* faces rather than the average block. On closure the enrollee escapes to another open block at the market price if they can still pass underwriting, and is otherwise trapped and rides the ramp. Escape probabilities are the age-specific CSG-rule pass rates of Appendix E (49.6% at 65–74, 33.1% at 75+), mortality is the age-band schedule of the MCBS pool, and premiums are discounted at 0.03.

Two modeling choices carry the result. First, escape is drawn *once*, at the moment of closure, not re-drawn each year: failing underwriting is a persistent personal characteristic, not an annual lottery, and treating it as iid lets almost everyone escape within a few years and drives the estimated harm to nearly zero ($32 rather than $802). Second, the ramp is the aging-netted wedge of Appendix B rather than the raw one, since a closed block's pool ages while an open block refreshes and part of the measured ramp is therefore the age curve rather than extraction.

A healthy entrant expects to pay $802 more in present value over their remaining lifetime because deadpooling exists, against $37,002 in the no-deadpooling counterfactual. Because every deadpooled premium scales with the entry price, an entry discount d scales the whole path, and there is a discount at which the entrant is exactly indifferent:

$$d^* = \frac{-PV_{\text{excess}}}{PV_{\text{cf}} + PV_{\text{excess}}}.$$

This is scale-free (the entry premium cancels) so it does not depend on how that premium is measured. Centrally $d^* = -2.1\%$: a successor would have to enter four percent below market to compensate a healthy 65-year-old for the closure risk they bear. The estimated entry discount is 2.5% with a confidence interval of $[-2.0, +7.0]$, entirely above that threshold. Across the grid of wedges and escape probabilities, every value of d^* is negative, so the healthy require some discount everywhere in the parameter space; the most generous cell available (the aging-immune wedge combined with a 95% escape probability, the rate the model itself assigns to its healthy consumers) still gives $d^* = -0.6\%$ and $228 of expected excess. Under no parameterization does the model's assumed 48.5% discount approach break-even.

I Appendix: Letter-Matched Controls

Appendix P.4 identifies plan letter as the covariate that breaks `csdid`'s default propensity model. There are two ways to hold plan letter fixed. One is to adjust for it, which is what the covariate specification does and what `drimp` makes feasible. The other is to match on it, comparing each closing block only to never-closing blocks of the same letter, so that the letter never enters the propensity model at all. The two routes share no estimating machinery, which makes their agreement (or disagreement) informative about the adjustment

rather than about either estimator. This appendix reports the matched version, as a robustness check on the covariate-adjusted closure estimates of Table 2 in the main text.

I.1 The interaction is not available as a covariate

The natural way to let each plan letter carry its own time path is a letter × year interaction. That is not estimable inside `csdid`: the documentation is explicit that only base-period covariate values are used, and within a single $ATT(g,t)$ the base period is a single year, so a letter × year term collapses to letter and adds columns collinear with the letter dummies already present.

The saturated cross-section version, `i.state##i.standnum`, is estimable in principle and fails in practice. Under `drimp` it separates completely: 100% of group-time cells are omitted in all 6 fits (premiums, profit and loss ratio, both panels) and the command reports a sample size of zero.

The reason is arithmetic rather than numerical, and it follows from where `csdid` fits the propensity model: separately inside each $ATT(g,t)$ cell, using cohort g's treated blocks against the never-treated pool. The saturated interaction contributes one column per occupied state × letter stratum, of which there are 472. The never-treated pool is not the binding constraint—it occupies 465 of those 472 strata, so controls are available almost everywhere. The treated side is. Of the 40 closure cohorts, 31 have *fewer treated blocks than there are strata* (median 190 blocks against 472 columns), so for those cells the propensity model has more parameters than treated observations and nothing is identified. The larger cohorts fail for the second reason: a cohort's treated blocks occupy a median of only 27.2% of the strata, and at most 71.8%, so the remaining strata contain never-treated blocks and no treated one. Each such dummy predicts non-treatment perfectly, which is complete separation, and the tilting problem has no interior solution. Both counts are computed pooling over time, so they *overstate* the overlap available inside any single (g,t) cell, where the treated blocks must also be observed in both the base period and t. Inverse probability tilting extends how much conditioning a propensity model will bear, but it cannot manufacture treated variation in a stratum that contains none. The interaction therefore has to come from the design.

I.2 Matching the control group on plan letter

We estimate the closure effect separately within each standardized letter, using `drimp` and never-closing blocks of that same letter as controls, and combine the ten estimates with enrollment weights. Because treated and control blocks share the letter, any letter-specific year effect differences out exactly. Table A6 reports the result, with and without state fixed effects inside each stratum, against the Column 3 estimates of Table 2 that it is checking.

For deadpooling closures the matched premium estimate is \$1,012, against \$1,005 from the fully adjusted specification of the main-text closure estimates (Table 2)—a difference of \$7, or 0.7%. Profit agrees to \$4 (0.9%). Two procedures with no machinery in common, one conditioning on plan letter and one holding it fixed by construction, land within one percent of each other. This is stronger corroboration of the adjusted specification than the outcome-regression check in Appendix P.4, which shares the propensity-free comparison but not the design. The exception is the non-deadpooling premium, where the matched estimate of \$365 sits 10.8% above the adjusted \$329; non-deadpooling profit agrees to 1.6%. The deadpooling–non-deadpooling contrast that the paper rests on is, if anything, slightly larger under matching.

Table A6. Letter-Matched Controls Reproduce the Covariate-Adjusted Estimate

	Non-deadpooling		Deadpooling	
Outcome	Letter-matched	Letter-matched	Letter-matched	Letter-matched
Per-person premiums	365	333	1,012	954
	(145)	(146)	(199)	(202)
Per-person claims	185	147	610	579
	(82)	(88)	(114)	(126)
Per-person profit	180	186	402	375
	(68)	(66)	(89)	(79)
Loss ratio	-0.025	-0.029	-0.057	-0.054
	(0.010)	(0.011)	(0.017)	(0.015)
State FE		X		X

Notes: Each entry is an enrollment-weighted combination of ten within-letter Callaway–Sant'Anna estimates, each comparing closing blocks of one standardized letter to never-closing blocks of the same letter, estimated by `drimp`. The second column of each pair adds state fixed effects inside the stratum, and is reported as a check rather than as an improvement: within a single letter `i.state` is 47 dummies fitted on roughly a tenth of the panel, so the doubly-robust estimator drops cohort-period cells for want of overlap and the state-adjusted estimate rests on a smaller base than the letter-matched one beside it. Where the two columns disagree, the difference can therefore reflect a changed sample as much as a changed adjustment. Parenthesised figures are standard errors clustered on the insurer, computed from `csdid`'s influence functions rather than by re-estimation: each block's influence on its letter's aggregate is scaled by that letter's enrollment weight and summed within insurer, so an insurer's contributions from different letters add before being squared. That cross-letter covariance is what makes these standard errors correct rather than conservative—the letter strata partition the blocks, but insurers sell many letters, so treating the strata as independent understates the variance. The procedure was validated by reproducing `csdid`'s own within-letter estimates and standard errors exactly. A 999-replication Mammen multiplier-bootstrap percentile interval over insurers was also computed and agrees with these standard errors; it is not shown, to keep one measure of uncertainty per cell. Clustering raises the standard errors by factors of 1.02 to 1.48, and by more in the deadpooling panel (up to 1.48) than the non-deadpooling one (up to 1.11), which is expected: deadpooling is concentrated in a few large parents that sell across many letters. 15 of the 16 intervals exclude zero; the exception is per-person claims for non-deadpooling closers with state fixed effects, which is the one cell in the table that cannot be distinguished from zero. Plan M is retained for completeness though its estimates are unreliable; excluding it changes no entry in this table at the precision shown.

Because the ten strata partition the blocks and are estimated separately, the pooled standard error must account for correlation across strata induced by insurers operating in several of them at once; we obtain it by clustering the stacked influence functions on insurer rather than re-estimating.

We do it that way because a literal block bootstrap would require roughly sixty `csdid` fits per replication (several hundred hours) while the influence functions `csdid` already computes deliver the same clustering in one pass.

Within a single letter `i.state` is 47 dummies fitted on a tenth of the panel, so the doubly-robust estimator drops cohort-period cells for want of overlap and the surviving estimate rests on a smaller base than the letter-matched specification. That is why we report the letter-matched estimate as the primary one and treat the state-adjusted variant as a check rather than an improvement.

I.3 Matching does not repair the pre-trends

The matched design leaves the parallel-trends verdict of Appendix P.4 intact. In the deadpooling panel the premium pre-trend fails for Plan F, which carries the most enrollment of any letter in the paper, under both specifications and at $p < 0.001$; only 2 of the ten letters pass, and adding state fixed effects changes no verdict there. The non-deadpooling panel is less stable—4 letters pass under letter matching alone and 3 once state effects are added, with three letters changing side, Plan F among them in the favourable direction. That last flip is worth isolating: Plan F loses no cells to the state dummies in either panel, so its non-deadpooling reversal is an adjustment effect rather than a changed sample. It has no counterpart in the deadpooling panel,

which is the one the paper's claim rests on. Whatever generates the pre-closure premium divergence there, it is not a letter composition effect that matching removes, and it is not geography.

Plan G is the one large letter whose premium path is flat before closure, and comfortably so. G is also the letter with the least statutory interference in its availability over the sample period, which is consistent with the interpretation in Appendix P.4 that the pre-trend is bound up with the changing menu of plans rather than with closure itself. We note the pattern without resting anything on it: one letter is one letter.

The loss ratio again behaves better than the levels, though less cleanly than on the full panel. It satisfies parallel trends for Plan F under both specifications, and in the non-deadpooling panel for 5 of the ten letters under letter matching alone and 4 with state effects added. Its one reversal is instructive: Plan G's loss-ratio pre-trend passes in the letter-only specification and fails once state effects are added—in exactly the letter that loses a quarter of its cells to those effects. That is the failure mode of Appendix P.4 reappearing at letter scale, and we read the reversal as a consequence of the deleted cells rather than as evidence about Plan G.

J Appendix: Deadpooling and Own Medicare Advantage Presence

Medicare Advantage is the main alternative to a Medigap policy, and most of the parents in our data sell both. That invites a natural question, which referees and seminar audiences have both raised: do insurers deadpool more aggressively in markets where they themselves have a larger MA presence, either because MA gives them somewhere to route the enrollees they price out, or because Medigap rents help fund MA expansion? We tested it and found nothing we are willing to report as a result. This appendix records the null so the question is not left open.

We build MA market share from the CMS State/County/Contract enrollment files, map contract-level organizations to their NAIC parent with a year-specific crosswalk, and collapse to the naicgroup $\times$ state $\times$ year level, matching the unit at which we measure deadpooling. The outcome is the share of a parent's Medigap lives in that state-year held in deadpooling plans; the regressor is the same parent's MA market share in the same state-year. Parents with no MA enrollment in a state-year are retained at zero share. Standard errors are robust, and we run every specification both unweighted and weighted by the parent's Medigap lives, since the two answer different questions—the average *cell* against the average *enrollee*.

The estimate is not stable across those two weightings, which is the substance of the null. Pooling all parents, a percentage point more own-MA share is associated with 0.621 more percentage points of deadpooled lives unweighted (s.e. 0.242, $p = 0.010$, $N = 34{,}874$), but -0.243 once cells are weighted by the enrollees actually exposed (s.e. 0.566, $p = 0.667$). The sign reverses and the significance disappears. Dropping UnitedHealth Group, which is both the largest MA insurer and the paper's never-deadpooling benchmark (Appendix F.2), does not settle it: the unweighted estimate is 0.605 ($p = 0.012$) and the weighted one -0.929 ($p = 0.184$). We read it as an association carried by small cells rather than by the enrollees the mechanism operates on.

The deeper problem is that there is very little variation to identify anything from. Once UnitedHealth Group is set aside, 99.6% of the remaining 34,058 parent $\times$ state $\times$ year cells have *zero* own-MA enrollment: the parents that dominate Medigap deadpooling are, with that one exception, largely not the parents selling MA in the same markets. Restricting to cells with any own-MA presence at all leaves $N = 141$, where the estimate

is 0.358 unweighted ($p = 0.194$) and 0.887 weighted ($p = 0.057$)—neither significant at conventional levels, and on a sample far too thin to carry a claim.

Two limitations bound what this test could have shown even in principle. The MA data do not cover every parent in the Medigap panel (one substantial Medigap writer does not appear in them at all, and Cigna exited MA partway through the sample) so the overlap is incomplete in a way that is not random. And the design is correlational: there is no source of exogenous variation in own-MA presence here, so even a stable coefficient would not have identified a cross-subsidy. We therefore treat the cross-market channel as untested rather than refuted, and nothing elsewhere in the paper rests on it.

K Appendix: Brand Distance Between Parent and Subsidiary

The mechanism requires that enrollees not connect the block that closed to the fresh block their parent opens next door. If that opacity were deliberate, it should leave a firm-side trace: a parent would route the strategy through subsidiaries whose names do not resemble its own. It does not. We classify each subsidiary as brand-similar or brand-dissimilar to its parent by stripping generic tokens from the parent's legal name in the NAIC parent–subsidiary map and testing whether any distinctive token survives in the subsidiary's name; ties and wholly generic parent names are coded *similar*, so the dissimilar group is never inflated by ambiguous cases.

The raw gap is composition. Dissimilar-named subsidiaries deadpool 31.0% of their plans against 25.3% for similar-named ones. That gap is between parents, not within them: Table A7 absorbs parent, state and plan-letter effects and the difference disappears. Deadpooling is a strict subset of closure, so the two rows of Panel A carrying opposite signs is itself a sign that neither is a real effect. Panel B asks whether a dissimilar-named block reprices its trapped pool harder, and finds nothing. Restricting to block-years after an acquisition (so that brand distance reflects a decision the current owner actually made) does not change the answer.

The two panels of Table A7 estimate, for plan p of subsidiary $s(p)$ under parent $f(p)$, in state $k(p)$ and plan letter $\ell(p)$,

$$Y_p = \beta\, D_{s(p)} + \alpha_{f(p)} + \gamma_{k(p)} + \delta_{\ell(p)} + \varepsilon_p, \tag{20}$$

$$P_{pt} = \beta\left(D_{s(p)} \times Post_{pt}\right) + \beta_0 D_{s(p)} + \beta_1 Post_{pt} + \lambda C_{pt} + \alpha_{f(p)} + \gamma_{k(p)} + \delta_{\ell(p)} + \tau_t + \nu_{pt}, \tag{21}$$

where D_s indicates a subsidiary whose name shares no brand token with its parent's, Y_p is an indicator that the plan deadpools (or ever closes), P_{pt} is per-enrollee premium, $Post_{pt}$ indicates years at or after the plan's closure, and C_{pt} is per-enrollee claims. Both are weighted by covered lives with standard errors clustered by subsidiary; the table reports β.

What the null does and does not settle. There is no firm-side evidence that parents select dissimilar-named subsidiaries to execute deadpooling. Two readings survive. The mechanism may not operate through naming at all—a parent needs only that the enrollee fail to shop, not that they fail to recognise a name. Or the measure may be too coarse to capture the kind of distance that matters to a senior reading a rate letter. We report the null rather than resolve between them. Note also that an earlier version of this test, run on data through 2020,

Table A7. Brand Distance Between Parent and Subsidiary Does Not Predict Deadpooling or Post-Closure Repricing

	All plans	Post-acquisition only
Panel A: plan-level linear probability model		
Deadpools	0.076	0.062
	(0.061)	(0.081)
Ever closes	−0.050	−0.034
	(0.091)	(0.112)
Panel B: per-enrollee premium, dissimilar × post-closure		
All plans	125.65*	116.34
	(73.41)	(82.81)
Closed plans	82.27	80.23
	(72.13)	(87.89)
Deadpooling plans	39.76	48.14
	(82.81)	(92.72)
Plans	17,364	13,796

Notes: All specifications absorb parent company, state and plan letter, are weighted by covered lives, and cluster standard errors at the subsidiary (NAIC) level; Panel B additionally absorbs calendar year. The regressor is an indicator for a subsidiary whose name shares no brand token with its parent's legal name, constructed as described in the text. Panel A collapses to one observation per plan, since both the outcome and the regressor are constant within a plan. Panel B is a plan-year panel and reports the coefficient on the interaction of the dissimilar-name indicator with an indicator for years at or after closure, controlling linearly for per-enrollee claims; the units are annual dollars per enrollee, inflation adjusted to January 2025. The right-hand column restricts to plans first observed at or after the year their subsidiary entered its current parent group, so that inherited pre-acquisition names cannot drive the result. Nothing in the table supports the brand-distance conjecture: within a parent, dissimilar-named subsidiaries are not detectably more likely to deadpool, are if anything less likely to close at all, and do not reprice their trapped pools more aggressively. The estimates are underpowered rather than precisely zero—the premium standard errors are of the same order as the coefficients—so a modest true effect would not be detectable here. * $p < 0.10$.

Table A8. Brand Distance Does Not Predict How Hard a Closed Block Is Repriced

Treated group	Per-person premiums	Per-person profit
Brand-similar subsidiaries	\$518	\$243*
	(\$323)	(\$131)
Brand-dissimilar subsidiaries	\$816***	\$347***
	(\$173)	(\$57)
Difference (dissimilar − similar)	\$298	\$104
	(\$367)	(\$143)
p-value	0.417	0.470
Memo: acquired subsidiaries	\$706***	\$319***
	(\$149)	(\$61)

Table A8 runs the closure event study separately within each brand-distance group. Read one arm at a time it appears to separate them, but the two arms' confidence intervals overlap throughout and the difference between them is not estimated, so the apparent contrast is not a finding.

Notes: Each arm is a separate Callaway–Sant'Anna estimate of the closure ATT, comparing closures by subsidiaries in that group to *all* never-closing blocks, with doubly-robust adjustment for state and plan type by inverse probability tilting (`drimp`), a universal base period (`long2`), NAIC-clustered standard errors and enrollment weights—identical to Table 2 except in which closers are treated. Brand similarity is the subsidiary-level classification used above; blocks whose parent is the company itself have no brand distance defined and enter neither of the first two arms. The difference row treats the arms as independent, which they are not: both are estimated against the same control group, so the reported standard error of the difference is a lower bound and its *p*-value is correspondingly generous to a finding of difference. The acquired row is a memo item rather than a third category—no acquisition indicator exists in these data, so "acquired" means a subsidiary whose parent identity changes during the panel, which overlaps both brand groups and can reflect a reporting reassignment as well as a sale.

found a marginal effect in the predicted direction; it does not survive the extension to 2025, which is the reason it is reported here rather than in the text.

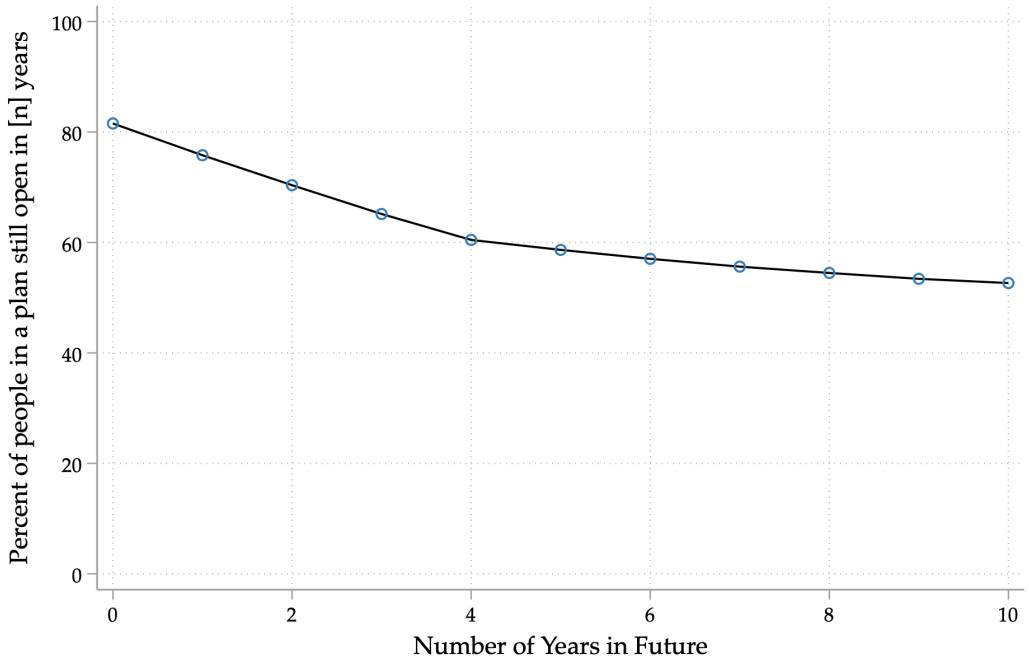

L Appendix: The Timing of Closure and Parent Reentry

Section 2.3 states the two headline exposure shares: 17.6% of life-years through 2020 are spent in a plan that deadpools, and about 38% of beneficiaries in a closing plan see their parent reenter within five years. This appendix reports the year-by-year timing behind the second figure, which is a detail of the construction rather than a result.

The timing also shows that reentry often *precedes* closure. 12% of enrollees in a closing plan are already in a block whose parent has opened a successor in the year before the closure takes effect—close to half of the 26% observed by the closure year itself. The successor is therefore frequently in place before the predecessor shuts, which is what one would expect if the closing and the opening are planned together rather than the opening being a response to the closing.

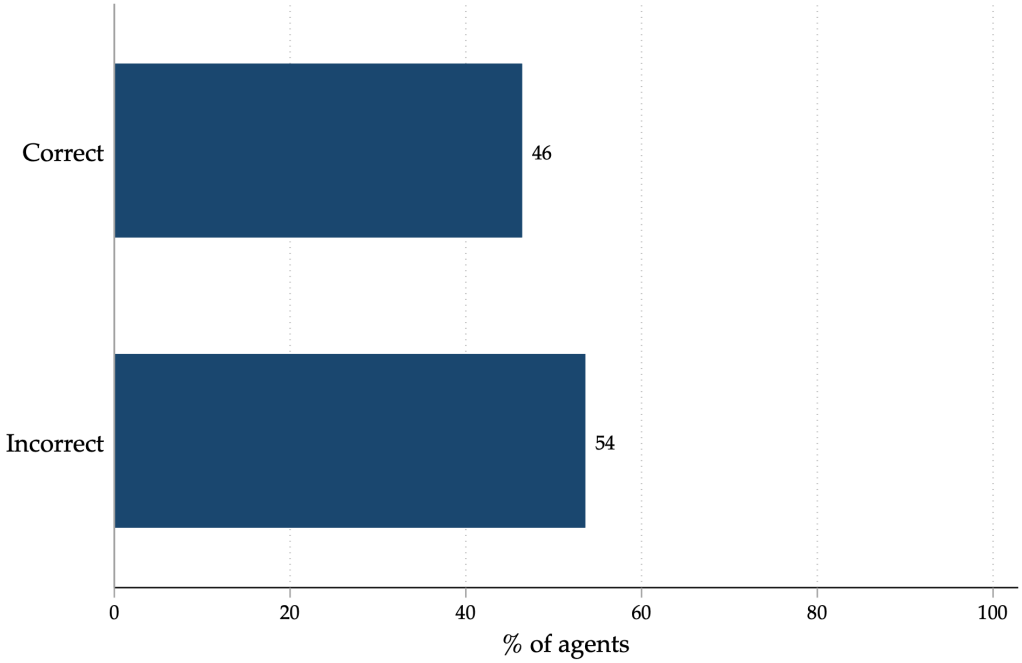

The companion timeline in Figure A5 shows how quickly plans close in the first place, tracing the share of enrollees whose plan is still open n years out. Closure is the common case rather than the exception, and the decline is steepest in the first few years—the same short open life that the four-year modal cycle in the main text reflects.

Figure A5. Nearly Half of Enrollees Are in a Plan That Closes Within Ten Years

Notes: Enrollment-weighted (by total lives): each point is the lives-weighted share of enrollees whose plan is still open [n] years in the future. Restricted to plans first appearing before 2015, so each can be followed a full ten years. The two slopes annotated on the figure are descriptive OLS slopes of the plotted series over event years 0–4 and 5–10 respectively; they are not estimates of a treatment effect. Closure is the common case, not the exception: 18% of enrollees are already in a closed plan at the left edge, and only 53% remain in a plan still accepting new members ten years out. The decline is steepest in the first four years, at about five percentage points a year, flattening to roughly one point a year thereafter.

Figure A6. Agent Knowledge of the MA-to-Medigap Underwriting "One-Way Door"

Notes: Share answering correctly that a client who switches from Medicare Advantage to Medigap later can be medically underwritten (and denied or surcharged). Agents who pass the survey's attention and invisible-text checks; $N = 306$ agents answered this item. Question asked: "A healthy 67-year-old in a Medicare Advantage plan asks: 'If I try MA now, can I switch to a Medigap plan in a few years if I don't like it?' How would you answer this question?"

M Data Integrity

Plan Choice Data Plan choice data are created from the NAIC Medicare Supplement Insurance Experience Exhibit data, which are annual statements that insurance companies are required to file in most states under the NAIC Medicare Supplement Insurance Minimum Standards Model Regulation. Medicare Supplement policies are defined as all forms which are qualified under the Federal Certification Requirements or the NAIC Medicare Supplement Insurance Minimum Standards Model Act and Regulation. While there is a small possibility of filing mistakes or missing data, since the annual filings are required by law the NAIC data is the highest quality data that exists and has been used in other research papers such as Maestas, Schroeder, and Goldman (2009) and Starc (2014). Cleaning of these data is deliberately light, because the filings are a statutory census rather than a sample and a dropped record is a lost block rather than a lost observation. We do not winsorize or trim the per-enrollee dollar outcomes used in the closure estimates; the one outcome we do winsorize is the loss ratio, at the first and ninety-ninth percentiles, because it is a ratio whose denominator can approach zero and whose raw upper tail therefore runs into the tens rather than reflecting anything about pricing. Blocks with no covered lives or no earned premium in a year cannot produce a per-enrollee outcome and are excluded from that year.

Panel Construction and Date Handling Dates are added to each year's data contemporaneously, so plans that close do not have closure dates in their earliest years in the panel. All dates are missing from the 2008 year of data. Date variables are assigned to the panel plan based on the maximum value observed in the data, since information like closure dates is often missing in early years when that information has not yet been determined. We link plans at the company $\times$ state $\times$ plan-letter $\times$ group-status level rather than the policy level, as many policies change their name over time. State restrictions on the number of plans a subsidiary can sell at once support this approach. Plans with nonconsecutive coverage years are dropped. This is a restriction on gaps in the *filings* and is distinct from the spell logic used to define deadpooling. The two are worth separating because they treat a gap in the data very differently. A *missing year* is an absence of filings: the block files in one year, does not file in the next, and files again later. That pattern is a data problem rather than a market event (we cannot tell whether the block existed in between) so those plans are dropped. A *spell* is the opposite case, where the block is present throughout but its behaviour indicates it was quietly reopened: enrollment in an already-closed block jumps by more than twenty percent and by at least fifty lives in a single year. Because an insurer can reopen a block without changing its NAIC code, treating such a series as one continuous block would average a closed period together with a fresh one. We therefore split it at each detected reopening and treat each spell as a distinct block, detecting reopenings iteratively until no further jumps are found. A genuine close-and-reopen cycle is thus retained rather than discarded, while a block with holes in its filing record is not. The restriction removes 4,196 plans, 17.7% of those in the collapsed panel, but only 4.2% of covered life-years, because the plans it drops are overwhelmingly small. Medicare SELECT plans are dropped. We also drop group plans except United Healthcare's AARP plans, as those are not available to all enrollees.

CSG Data Cleaning Insurance companies report their rates directly to CSG, and the firm then independently verifies the pricing information. CSG quotes vary within a plan letter by age, gender, tobacco use, and household or couple discount status. In this paper, we only consider non-tobacco rates. This understates what a smoker would be offered. Three further restrictions apply to the CSG data. We keep only the ten lettered plans fixed by statute, dropping pre-OBRA policies and the nonstandard plans sold in Massachusetts, Minnesota and Wisconsin, since those are not comparable across states and a plan letter does not mean the same thing in them. We drop records with no plan letter recorded. And we use the rate a plan posts for a standard applicant rather than any underwritten or rated-up figure, so a quoted price here is the price a clean applicant of that age would be charged, not the price someone with a flagged condition would be offered.

Parent–Subsidiary Mapping and Year Matching We use the NAIC *Listing of Companies* data to link companies to subsidiaries. Each block is assigned the parent recorded for its NAIC code in its own year to account for acquisitions. Codes that match no parent are treated as their own parent.

N Appendix: The Medicare Agent Survey

The NAIC and CSG data describe deadpooling from the insurer's side. To see how the intermediaries who actually place seniors into plans perceive and respond to it, we fielded a survey of licensed Medicare insurance agents. This appendix describes that instrument and reports its descriptive results; the survey is not used to identify any of the paper's causal estimates and is offered as corroborating supply-side evidence.

Data collected. The Medicare Agent Survey is a pilot fielded in 2026 through the Cint online research panel, screening for respondents who hold an active Medicare insurance license. We describe only the Medigap-relevant content here. A deadpooling module measures awareness of block closures, the perceived share of clients trapped on a closed block, beliefs about the underwriting outcomes those clients face, how often an agent weighs a carrier's closing history, per-carrier suspicion that a company actively deadpools, and what an agent would advise a client facing a large rate increase. A three-item knowledge screen tests whether agents know that switching from Medicare Advantage to Medigap later requires medical underwriting, that Original Medicare alone has no annual out-of-pocket maximum, and that same-letter Medigap benefits are standardized by law. The instrument also carries modules on agent demographics and book composition, client vignettes eliciting Medicare Advantage versus Medigap recommendations, a commission-gradient experiment, and existing-client service, which we describe no further because the paper does not draw on them.

Automated-response screening. Online agent panels are known to attract automated and low-effort responses, so the instrument embeds several traps and we report results across a graduated set of exclusion screens rather than a single cleaned sample. Two honeypots catch page-scraping bots: an instruction rendered in invisible text that asks the respondent to include a specific phrase (a human

never sees it; a bot that reads the page source often complies), and an off-screen link that only an automated agent would click. A third trap hides an instruction to write an implausibly long open-ended answer. Beyond these deterministic traps we flag near-verbatim open-ended answers shared across distinct respondents (a signature of answer farms and language-model output that within-respondent duplicate checks miss) as well as attention-check failures, the knowledge screen above, a reCAPTCHA bot score, and duplicate device and network fingerprints. Of 1,044 responses, 627 were complete. We report every descriptive across four nested analysis samples of completed responses: automated/bot responses removed only ($N = 614$); additionally excluding attention-check failures ($N = 476$); instead excluding failures of the three-item knowledge screen ($N = 410$); and a strict screen that removes attention, knowledge, straightlining, and low bot-score responses ($N = 366$). Each figure below shows its outcome under all four screens as a robustness panel; where an estimate shifts materially across screens we flag it, since the direction of that shift is itself informative about how automated responses bias the raw data.

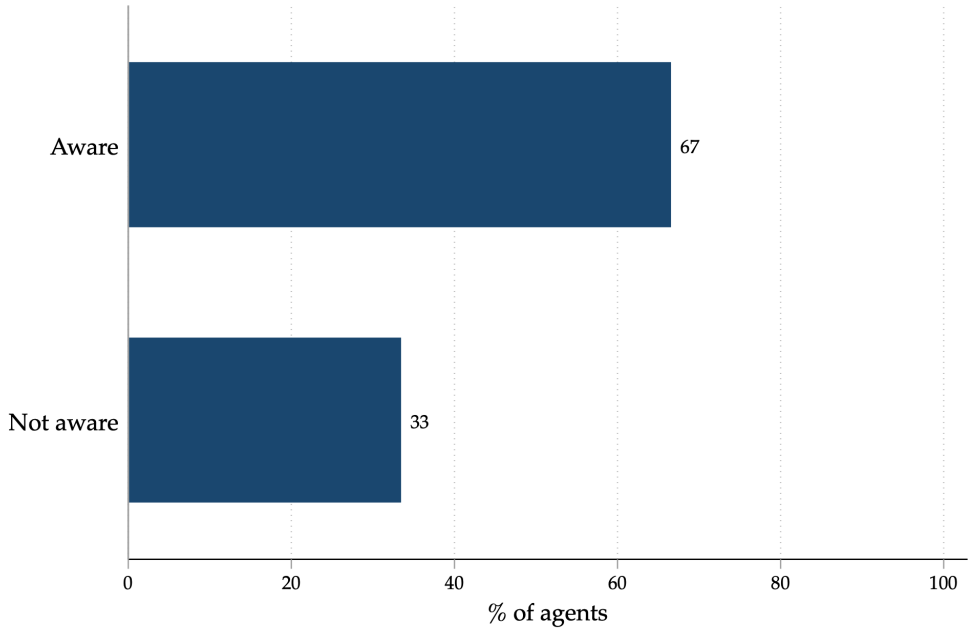

What the survey shows. Two patterns recur. First, agents are broadly aware of deadpooling and its consequences: a majority recognize block closures, and they estimate that a large minority of trapped clients are either offered underwritten Medigap only at uncompetitive rates or denied it entirely (Figures A7–A9). Second, agents' suspicion of specific firms is only loosely tied to which firms actually deadpool: the firms the NAIC data identify as deadpoolers draw suspicion at rates similar to firms that do not, including the market's largest never-deadpooling operator (Figure A11). We therefore read the firm-level figures as measuring the market's *perceptions* rather than as independent evidence on which firms deadpool, which is the task of the NAIC event studies. We also caution that the stricter screens leave small denominators for the modules shown only to post-pilot respondents, so cross-screen differences in those figures are directional rather than precise.

O Appendix: Summary Statistics by Switching Regime

Table 1 pools all states. Table A9 reports the same rows separately for the three regulatory regimes of Figure 1: open enrollment, where a beneficiary outside the Medigap market can buy in at least annually; an annual switching window, where a beneficiary already holding a policy can move; and no protection, where leaving requires passing medical underwriting. The regime is a state-year attribute, so a state that adopts a rule mid-panel contributes its pre-adoption years to Panel C and its post-adoption years to Panel A or B. The panels partition the sample exactly: their plan-block-year counts sum to the 186,561 of the main table.

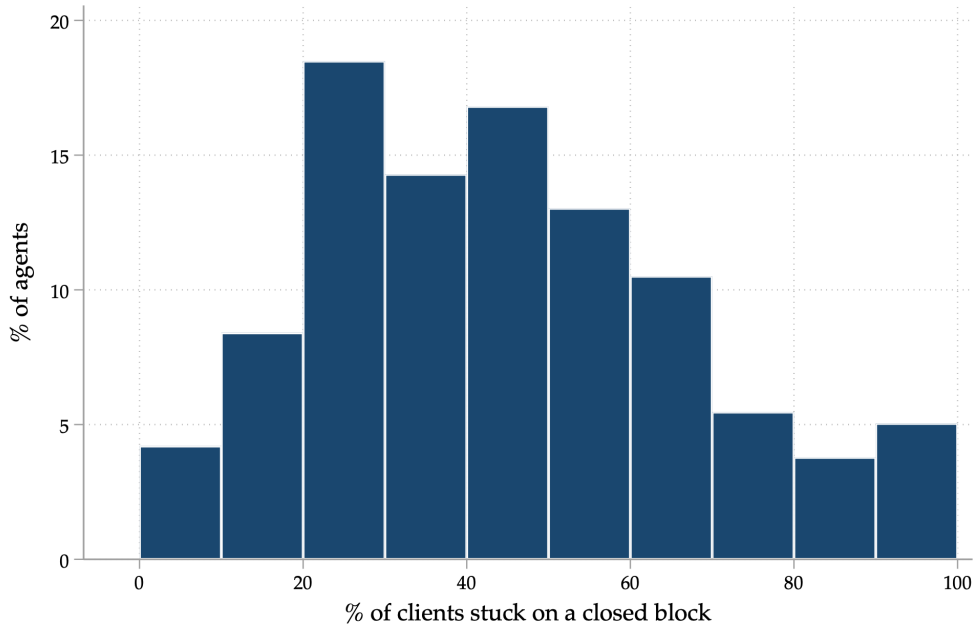

The point of the split is to show that the deadpooling pattern is not an artifact of the locked-in states, and that the pooled table is nonetheless dominated by them. The ordering that Section 6.1 draws from the pooled table holds in every panel: deadpooling blocks charge less than blocks that never close while they are open, charge more than either once they close, and lose most of their enrollment in between. What differs across panels is scale, not sign. The no-protection states supply 164,316 of the 186,561

Figure A7. Most Agents Are Aware of Deadpooling / Block Closures

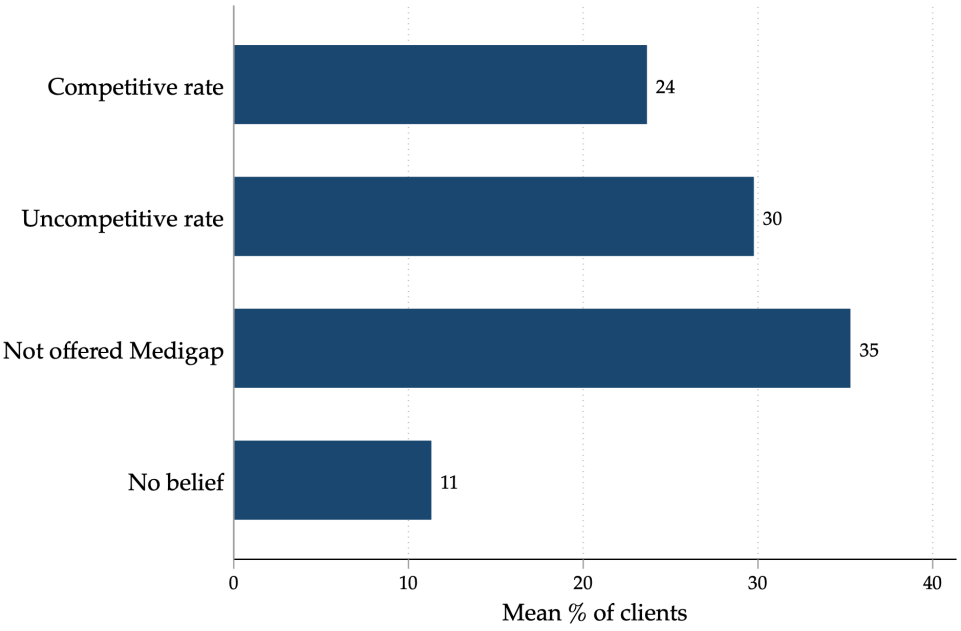

Notes: Share of agents aware that Medigap blocks close to new enrollment while continuing to insure incumbents. Agents who pass the survey's attention and invisible-text checks; $N = 305$ agents answered this item. Question asked: "Are you familiar with the practice of 'deadpooling', 'block exits', or 'subsidiary closures' where insurance companies close plans, concentrate high-cost enrollees together, raise premiums, and use subsidiary companies to open new books of business?"

Figure A8. Agents' Estimates of the Share of Clients Trapped on a Closed Block

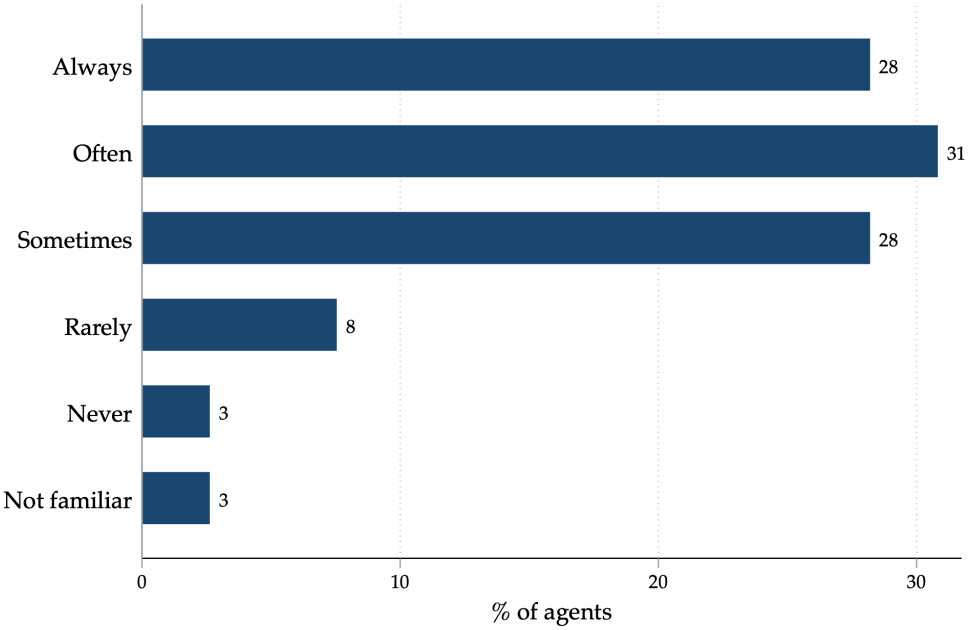

Notes: Distribution of each agent's estimate of the percentage of their Medigap clients currently stuck on a closed block. Agents who pass the survey's attention and invisible-text checks; $N = 238$ agents answered this item. Question asked: "Out of every 100 of your clients with a Medigap policy, about how many are stuck on a closed block paying above-market premiums?"

Figure A9. Perceived Underwriting Outcomes for Clients When a Block Closes

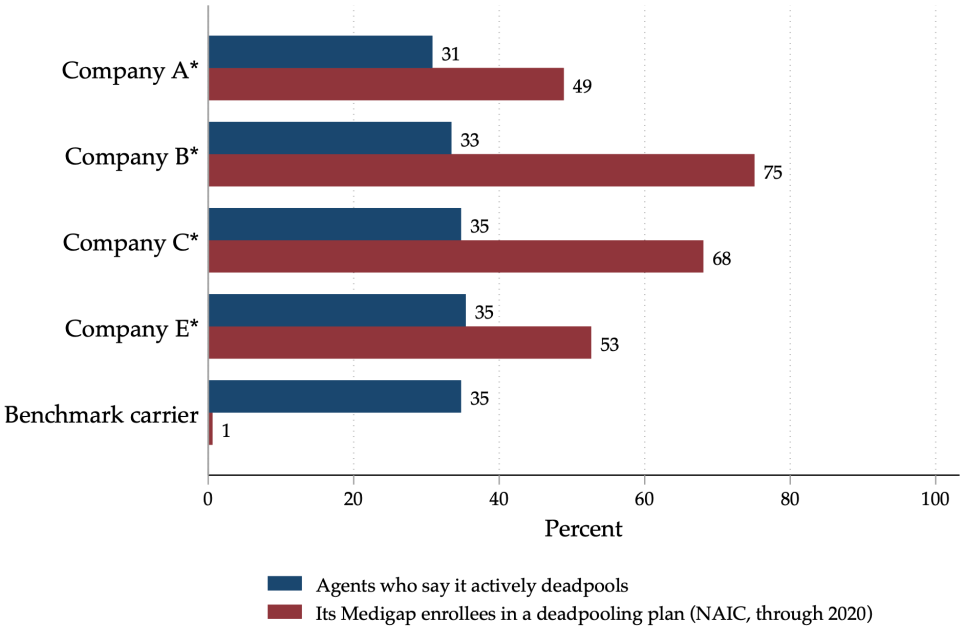

Notes: Mean share of clients an agent places in each underwriting outcome (offered underwritten Medigap at a competitive rate, at an uncompetitive rate, not offered, or no belief), elicited as a constant-sum battery. Agents who pass the survey's attention and invisible-text checks; $N = 305$ agents answered this item. Question asked: "Think about all of your current Medicare clients. If all of your clients were to apply for a Medigap plan, about how many would fall into each of the categories below? (The four estimates should sum to 100%.)"

Figure A10. How Often Agents Weigh a Carrier's Block-Closing History

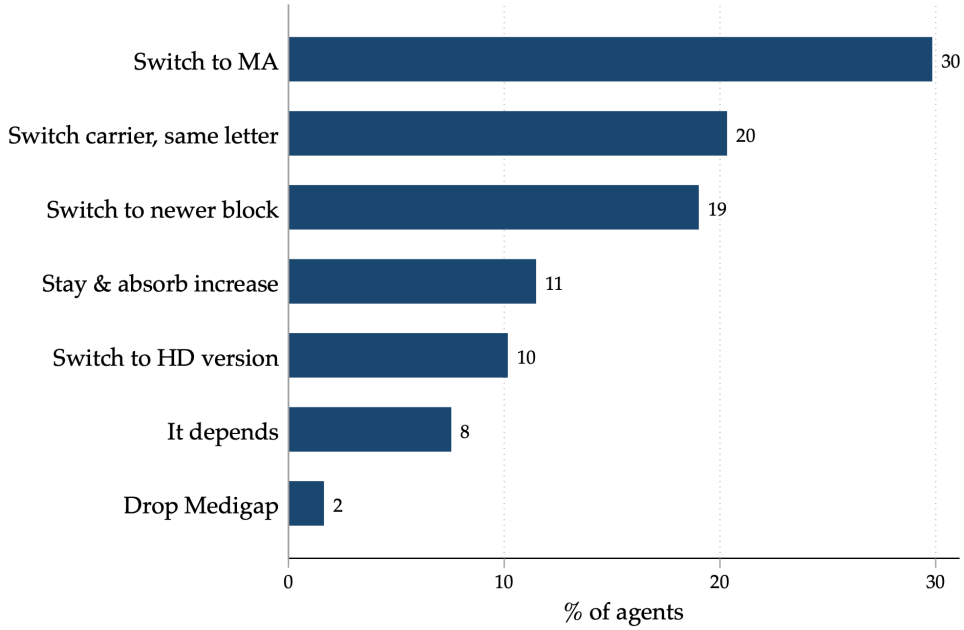

Notes: Share of agents choosing each frequency. Agents who pass the survey's attention and invisible-text checks; $N = 305$ agents answered this item. Question asked: "When recommending a Medigap plan, how often do you consider whether a carrier has a history of closing blocks and reopening new blocks under subsidiaries?"

Figure A11. Agents' Suspicion of Each Carrier Against Its Actual Deadpooling

Notes: Bars: share of agents rating each carrier as one that "actively deadpools" (rather than trusting it to keep blocks open, or unsure). Maroon: share of that carrier's Medigap enrollees (life-years) in a plan the NAIC data classify as deadpooling, filings through 2020. Carriers are anonymized; * marks an active deadpooler in the NAIC data; the benchmark is the largest carrier that never deadpools. Agents who pass the survey's attention and invisible-text checks; $N = 305$ agents answered this item. Question asked: "For each carrier below, indicate whether you believe the carrier actively engages in 'deadpooling' (closing Medigap blocks and reopening under new subsidiaries) or the carrier can be trusted to keep its blocks open."

Figure A12. What Agents Would Advise a Medigap Client Facing a Large Rate Hike

Notes: Share of agents choosing each recommendation. Agents who pass the survey's attention and invisible-text checks; $N = 305$ agents answered this item. Question asked: "Suppose the following client receives a 15%+ premium increase on their current Medigap plan. What would you recommend if the client is… a healthy 72-year-old client."

block-years and the open-enrollment states only 4,674, so the pooled means in Table 1 sit close to Panel C throughout. The open-enrollment states are also a different kind of market (354 blocks holding 1,977 enrollees on average, against 15,687 blocks averaging 757 where there is no protection) which is why their much higher premium levels move the pooled figures so little.

P Appendix: Robustness of the Closure Estimates

This appendix collects every robustness check on Table 2 in one place. The main estimates pool all standardized plan letters and weight by enrollment, and what follows asks whether the post-closure premium, claims, and profit increases are artifacts of thinly-enrolled blocks, of a single plan type, of which of `csdid`'s two doubly-robust estimators is used, of the closure dates we impute rather than read off the filings, or of a pre-existing divergence between closing and never-closing blocks. In order: the *minimum-enrollment screen*, the *plan-letter breakdown*, the *imputed closure dates* check, then Appendix P.1, *Pre-Trend Tests*, which reports the joint test of parallel trends for every panel and column; Appendix P.2, *Closure Estimates for Deadpooling and Non-Deadpooling Plans Together*, which shows the two arms side by side; Appendix P.3, *Clustering at the Parent Company*, which re-estimates the standard errors at the parent rather than the NAIC insurer; and Appendix P.4, *Estimator Choice*, which reports the same table under the alternative doubly-robust estimator `dripw`. Appendix P.7, *The Two-Way Fixed-Effects Analogue*, reports the same comparison under a conventional two-way fixed-effects specification. The letter-matched version of the same comparison is separate, in Appendix I.

Minimum-enrollment screen. Table A10 re-estimates the ATT on the full panel and on the panel with block-years of fewer than ten covered lives removed. Because the estimator is enrollment-weighted, these small blocks carry almost no weight and dropping them barely moves the estimates: the per-person premium ATT goes from \$720 to \$753, claims from \$404 to \$419, and profit from \$316 to \$333, each larger again for deadpooling plans, exactly as in the main text. The screen is equally immaterial under the paper's own estimator (Table A11), where the premium ATT moves from \$643 to \$645.

The two doubly-robust estimators. Table A10 uses `csdid`'s default doubly-robust estimator, inverse-probability-weighted regression adjustment (`dripw`). Table A11 repeats all three columns under inverse probability tilting (`drimp`), which is the estimator Table 2 and the rest of the paper use. We show both because the choice is consequential here in a way it is not elsewhere, and because the difference is informative about the sample rather than about the estimand. The two agree on every sign and on the ordering the paper rests on (deadpooling closers move more than closers generally, in premiums, claims, and profit alike) but not on magnitude or precision. Pooled over all closers the premium ATT is \$720 under `dripw` against \$643 under `drimp`; for deadpooling closers, \$1,362 against \$1,005. `drimp` returns the smaller point estimates and the substantially smaller standard errors, so every cell significant at ten percent in the first table is significant at one percent in the second.

The reason is the estimation sample. `dripw` fits a logit propensity model and discards any cohort-period

Table A9. Summary Statistics by State Switching Regime

	Means by block status				
	Full sample	Open, DP	Closed, DP	Non-DP, all	Never close
Panel A: Open enrollment (annual guaranteed entry to the market)					
CSG: Quoted rates, 2014–2025					
Annual rate, age 65	$3,360	—	$3,898	$3,359	$3,336
Annual rate, age 70	$3,360	—	$3,898	$3,359	$3,336
Annual rate, age 75	$3,360	—	$3,898	$3,359	$3,336
Annual rate, age 80	$3,360	—	$3,898	$3,359	$3,336
Annual rate, age 85	$3,360	—	$3,898	$3,359	$3,336

Parent companies	220	104	119	214	134

Notes: Same panel, column definitions, weighting, deflator, CSG construction and five-year lookforward cutoff as Table 1; the three panels differ only in which state-years they retain, and between them they exhaust the sample. Panel C is the sample on which every mechanism test in the paper is run. Premiums, claims and profits are per enrollee and enrollment-weighted, dollar figures are in January 2025 dollars, and the loss ratio is total claims divided by total premiums. CSG rows are the equal-weight mean of the male and female non-smoker quote, 2014–2025 only, with closed blocks that are no longer quoted priced at their renewal schedule. A dash marks a cell with no CSG price. The open-enrollment states community-rate Medigap, so their quote does not vary with age.

Table A10. The Closure Effect Survives a Minimum-Enrollment Screen

Table R1: Robustness of the Plan-Closure ATT to a Minimum-Enrollment Screen

	(1) Baseline	(2) Drop <10 lives	(3) Drop 2010 closers
Panel A: Per-Person Premiums (2025 $)			
Closure, Any Plan	719.67*	752.66*	719.67*
	(384.51)	(403.82)	(384.51)
Closure, Deadpooling Plans Only	1361.55**	1439.42**	1361.55**
	(615.42)	(627.72)	(615.42)
Panel B: Per-Person Claims (2025 $)			
Closure, Any Plan	403.55*	419.29*	403.55*
	(243.38)	(249.78)	(243.38)
Closure, Deadpooling Plans Only	813.79**	863.04**	813.79**
	(362.75)	(372.97)	(362.75)
Panel C: Per-Person Profits (2025 $)			
Closure, Any Plan	316.12**	333.37**	316.12**
	(147.85)	(157.66)	(147.85)
Closure, Deadpooling Plans Only	547.76**	576.38**	547.76**
	(266.16)	(264.95)	(266.16)
State controls	X	X	X
Plan Type controls	X	X	
Never-treated control	X	X	
Doubly-robust DR	X	X	
N (Unique Plans)	131,153	88,422	
N (Unique Plans, Deadpooling Only)	89,129	66,935	

Notes: Each column re-estimates the Table 1 doubly-robust Callaway–Sant'Anna (2021) specification (state and plan-type controls, never-treated control group, enrollment weights) on a different sample, using csdid's DEFAULT doubly-robust estimator, inverse-probability-weighted regression adjustment (`dripw`) – not the `drimp` used in Table 1. Column (2) drops the 36% of block-years with fewer than 10 covered lives; because the estimator is enrollment-weighted these observations carry almost no weight, so the point estimates barely move. Dropping the modal 2010 closure cohort leaves the estimates unchanged and is not shown: under the doubly-robust controls csdid omits that collinear cohort entirely, so the main estimate does not use the 2010 closers to begin with. Standard errors in parentheses are csdid analytic influence-function SEs clustered at the NAIC insurer level. *** p<0.01, ** p<0.05, * p<0.10.

cell in which the state and plan-type controls perfectly separate treated from never-treated blocks; tilting does not, and retains them. That leaves $N = 131{,}153$ block-years in the first table against $N = 191{,}412$ in the second. Since the discarded cells are precisely the small, thinly-covered state $\times$ letter $\times$ cohort combinations where closure is most concentrated, the `dripw` estimates rest on a narrower and more variable slice of the data, which is what produces the wider intervals. We read the agreement in sign and ordering as the substantive result and prefer `drimp` for the reported estimates on sample-retention grounds; readers who prefer the default estimator can take Table A10 instead, and nothing in the paper's argument turns on the choice.

The modal closure cohort. Column 3 of each table drops the 2010 closure cohort. Under `dripw` its cells are identical to Column 1 in every panel (not merely close, but the same coefficient, the same standard error, and the same estimation sample of $N = 131{,}153$ block-years) because the per-cohort comparisons for the 2010 group are collinear under the doubly-robust controls, so that estimator never uses those closers and removing them changes nothing. That makes the `dripw` column a tautology rather than a test. Under `drimp` the cohort is retained, so its Column 3 is the real check, and it is the one to read: dropping 2010 lowers the pooled premium ATT from \$643 to \$577 and the deadpooling premium ATT from \$1,005 to \$842, with claims and profit moving in step and every cell still significant at one percent. This is worth showing rather than asserting, because the cohort is not small (blocks closing in 2010 hold 31.4% of all closer lives) so the natural worry is that the headline estimate rests on one unusual year. It does not: removing that year leaves an effect that is smaller but still large and precisely estimated.

Imputed closure dates. A block's closure year is read off the filings where the filings record it and imputed where they do not. Because the imputation is what defines treatment timing for those blocks, it is worth knowing how much of the closure result depends on it. We re-estimate the event study of Figure 3 on recorded closers alone, dropping every block whose closure year is imputed, which removes about a tenth of the panel ($N = 191{,}412$ to $N = 171{,}834$).

The post-closure path does not move at all. Averaged over the window the ATT is \$461.31 as published against \$463.55 on recorded closers, and from $t + one$ onward the two runs agree to the printed decimal in every one of the 5 remaining event times—the same coefficients and the same standard errors, not merely similar ones. The identity is mechanical, and that is the point: an imputed closure is inferred near the end of the panel, so those blocks contribute pre-period and $t = 0$ observations and essentially nothing afterwards. The premium increase we estimate therefore cannot be an artifact of the imputation, because the imputed blocks are not in the post-period that identifies it.

What does move is the pre-period, slightly and in the reassuring direction. The average pre-closure coefficient goes from \$-134.38 (s.e. 48.96) to \$-125.76 (s.e. 52.58), and at $t - 4$ the estimate crosses out of conventional significance ($p = 0.023$ to $p = 0.053$). It does not disappear: the average stays negative and significant, and $t - 3$ and $t - 2$ remain significant on recorded closers alone. The pre-trend documented in Appendix P.4 is thus a property of closing blocks rather than a consequence of how we date the closures.

Table A11. The Same Screens Under Inverse Probability Tilting

Table R2: The Same Screens Under Inverse Probability Tilting (drimp)

	(1) Baseline	(2) Drop <10 lives	(3) Drop 2010 closers
Panel A: Per-Person Premiums (2025 $)			
Closure, Any Plan	642.87***	645.35***	576.91***
	(196.82)	(198.21)	(203.95)
Closure, Deadpooling Plans Only	1004.52***	1008.11***	842.18***
	(235.39)	(236.85)	(221.52)
Panel B: Per-Person Claims (2025 $)			
Closure, Any Plan	359.27***	357.68***	317.16**
	(118.81)	(120.01)	(123.81)
Closure, Deadpooling Plans Only	606.19***	609.78***	512.49***
	(139.06)	(139.16)	(130.35)
Panel C: Per-Person Profits (2025 $)			
Closure, Any Plan	283.60***	287.67***	259.75***
	(80.95)	(81.00)	(82.34)
Closure, Deadpooling Plans Only	398.33***	398.34***	329.70***
	(99.98)	(101.25)	(95.73)
State controls	X	X	X
Plan Type controls	X	X	X
Never-treated control	X	X	X
Doubly-robust DR	X	X	X
N (Unique Plans)	191,412	124,679	150,507
N (Unique Plans, Deadpooling Only)	111,097	81,230	99,573

Notes: Each column re-estimates the Table 1 doubly-robust Callaway–Sant'Anna (2021) specification (state and plan-type controls, never-treated control group, enrollment weights) on a different sample. Column (2) drops the 36% of block-years with fewer than 10 covered lives; because the estimator is enrollment-weighted these observations carry almost no weight, so the point estimates barely move. Column (3) drops the modal 2010 closure cohort. Under `dripw` that cohort is collinear and is discarded before estimation, so dropping it is not a test; inverse probability tilting retains it, and the estimates fall while every cell stays significant, all but one at one percent. Standard errors in parentheses are csdid analytic influence-function SEs clustered at the NAIC insurer level. *** p<0.01, ** p<0.05, * p<0.10.

Restricting to states without switching protections. A natural worry about the pooled event study is that it mixes states where a healthy enrollee could simply have left after closure with states where she could not, and that the resulting heterogeneity inflates the standard errors. We re-estimate the identical specification on regime-3 block-years alone—states with no guaranteed-issue or annual-switching right, where the lock-in the mechanism relies on is actually present. The restriction does not help precision: averaged over the post-closure window the standard errors are *wider*, by 7% for premiums, 8% for claims, 6% for profit and 11% for the loss ratio (8% across all four). That is the expected direction: the restriction discards control observations without removing a corresponding source of noise. What it does deliver is reassurance about the point estimates, which barely move—the restricted ATTs track the pooled ones closely at every event time and are, if anything, slightly larger. The pooled figure is therefore not being driven by states in which enrollees had an exit.

The same check on the sharpened big-company comparison of Figure A4 gives the same answer, which is what makes it informative rather than incidental. There the standard errors are 8% wider for premiums, 9% for claims, 5% for profit and 6% for the loss ratio (7% across the four), and the point estimates again barely move: five years out, premiums go from \$1,149 to \$1,203 and profit from \$499 to \$505, while the loss ratio shifts by two thousandths. Two event studies with different treated groups and different control groups therefore agree that the restriction costs precision without changing the conclusion, so we report the pooled specifications throughout and treat the regime-3 versions as a check that passes.

P.1 Pre-Trend Tests

Identification in Table 2 rests on parallel trends, and this section reports the test of it for every panel and column. Each entry is a joint Wald test that all five pre-treatment event-time effects ($t = -6$ to -2; $t = -1$ is the base period) are zero, following equation (6), so a *large* value is the favourable outcome. The test is run on event-time aggregates rather than on the individual cohort-period cells, whose cluster-robust covariance is rank-deficient here (Section 5). Both arms are shown: the deadpooling plans of the main table, and the non-deadpooling closers of Appendix P.2.

The two arms behave differently under the test, and the difference governs how we read the table. For non-deadpooling closers, every outcome passes comfortably in Column 3 (0.104 for premiums, 0.341 for claims, 0.180 for profit, 0.452 for the loss ratio). For deadpooling closers the picture is mixed, and it splits by outcome rather than uniformly. Premiums and claims reject at the five percent level in *every* column, Column 3 included (0.004 and 0.025), and the covariate adjustments do not rescue them. Profit and the loss ratio, by contrast, fail to reject in every column (0.188 and 0.260 in Column 3). Appendix P.4 shows that the failure is a property of these blocks rather than of the estimator: it appears under both doubly-robust estimators.

Table A12. Joint Pre-Trend Tests for the Closure Estimates

		(1)	(2)	(3)
Premiums	Deadpooling	0.000	0.001	0.004
	Non-deadpooling	0.002	0.112	0.104
Claims	Deadpooling	0.000	0.006	0.025
	Non-deadpooling	0.010	0.082	0.341
Profits	Deadpooling	0.263	0.327	0.188
	Non-deadpooling	0.025	0.637	0.180
Loss ratio	Deadpooling	0.362	0.448	0.260
	Non-deadpooling	0.828	0.952	0.452

Notes: p-values from a joint Wald test that the five pre-treatment event-time effects ($t = -6$ to -2; $t = -1$ is the base period) are all zero, run on the event-time aggregates. A large value is the favourable outcome, so the entries are deliberately unstarred: a small value is evidence against the specification rather than for it. Columns match Table 2: (1) no covariates, (2) state, (3) state and plan type. Estimator is `drimp` with a universal base period (`long2`), enrollment-weighted, standard errors clustered at the NAIC insurer level.

P.2 Closure Estimates for Deadpooling and Non-Deadpooling Plans Together

Table 2 in the main text reports the closure estimates for deadpooling plans only. This appendix reproduces the same specification with both arms shown together: the deadpooling plans and, as a separate row in each panel, the disjoint set of plans that close without their parent reopening. The two groups are mutually exclusive, so the rows can be read against one another directly.

The contrast is sharpest in columns 1 and 2, where both arms are precisely estimated and the deadpooling effect is two to three times larger. In column 3 the non-deadpooling arm loses most of its precision, and the reason is mechanical rather than substantive: adding the plan-type adjustment to the propensity model drops every cohort-year cell before 2011 on that arm, which removes the 2010 closure wave—the largest in the panel. The estimates in that column should be read with that in mind.

P.3 Clustering at the Parent Company

The main closure estimates cluster standard errors at the NAIC insurer (Section 5). Many insurers belong to a larger parent group, and a parent can set pricing and closure policy across all of its subsidiaries at once, so shocks may be correlated across sibling insurers as well as within one. This appendix re-estimates the closure exhibits with standard errors clustered at the parent company instead.

Defining the parent. Parent assignments change over the panel as insurers are bought and sold, so many blocks carry more than one parent code over their lives. The Callaway–Sant'Anna estimator requires every block to sit in a single cluster, so we assign each block its *modal* parent: the parent group under which it carried the most covered lives over its whole life. Everything else—sample, weighting, covariates, estimator (`drimp`) and universal base period—is identical to Table 2, so every point estimate is unchanged and only the standard errors, significance stars and pre-trend tests can move.

Results. For deadpooling closers (Table A14) every estimate remains significant at the one percent level for premiums, claims and profit in every column, and the loss-ratio estimates become more precise rather than less.

Table A13. Closure Estimates, Deadpooling and Non-Deadpooling Plans

	(1)	(2)	(3)
Panel A: Per-Person Premiums (2025 $)			
Closure, Deadpooling Plans Only	$1,116***	$1,049***	$1,005***
	(242)	(236)	(235)
Closure, Non-Deadpooling	$341**	$344**	$329**
	(139)	(150)	(161)
Pre-closure mean: $2,347 (deadpooling); $2,746 (non-DP)			
Pre-trend holds, deadpooling			
Pre-trend holds, non-deadpooling		X	X
Panel B: Per-Person Claims (2025 $)			
Closure, Deadpooling Plans Only	$724***	$676***	$606***
	(139)	(146)	(139)
Closure, Non-Deadpooling	$195**	$167**	$146
	(79)	(81)	(96)
Pre-closure mean: $1,821 (deadpooling); $2,161 (non-DP)			
Pre-trend holds, deadpooling			
Pre-trend holds, non-deadpooling		X	X
Panel C: Per-Person Profits (2025 $)			
Closure, Deadpooling Plans Only	$392***	$373***	$398***
	(107)	(96)	(100)
Closure, Non-Deadpooling	$147**	$177**	$183***
	(70)	(75)	(71)
Pre-closure mean: $526 (deadpooling); $585 (non-DP)			
Pre-trend holds, deadpooling	X	X	X
Pre-trend holds, non-deadpooling		X	X
Panel D: Loss Ratio (claims / premiums)			
Closure, Deadpooling Plans Only	-0.035*	-0.038**	-0.056***
	(0.019)	(0.015)	(0.018)
Closure, Non-Deadpooling	-0.006	-0.026**	-0.029***
	(0.019)	(0.012)	(0.010)
Pre-closure mean: 0.795 (deadpooling); 0.796 (non-DP)			
Pre-trend holds, deadpooling	X	X	X
Pre-trend holds, non-deadpooling	X	X	X
State controls		X	X
Plan type controls			X
N (plan-block-years, deadpooling only)	111,097	111,097	111,097
N (plan-block-years, non-deadpooling)	150,222	150,222	150,222
Unique blocks (deadpooling / non-deadpooling)		12,478 / 14,692	
Subsidiaries (deadpooling / non-deadpooling)		291 / 322	
Parent companies (deadpooling / non-deadpooling)		207 / 236	

Notes: Specification, sample, weighting, clustering, estimator (`drimp`) and pre-trend tests are identical to Table 2; see that table's note. The only difference is that both arms are displayed. "Closure, Deadpooling Plans Only" is the row reproduced in the main text. "Closure, Non-Deadpooling" restricts to plans that close and whose parent does not open a successor in the same market within five years; deadpooling closers are dropped from that arm's sample entirely rather than left in as controls, so the two rows are disjoint groups rather than a subset and its superset. Standard errors clustered at the NAIC insurer level in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

Why coarser clusters give smaller standard errors. Clustering on a coarser unit can shrink a standard error only if the contributions of sibling insurers to the estimate are negatively correlated. Decomposing the estimator's influence function by insurer shows that the shrinkage in the deadpooling arm comes entirely from a single large parent group, whose subsidiaries' contributions largely offset one another. Most of the offset is between the deadpooling closures of that group's different subsidiaries; a smaller part is between one subsidiary's closures and a sibling subsidiary's never-closing blocks, which is the pattern that closing a block in one subsidiary while selling a successor in another would produce. Across every other parent the cross-subsidiary terms are small and slightly positive, so without that group parent clustering would widen the intervals a little, as one would expect. The parent-clustered standard errors for this arm therefore rest heavily on one group's internal covariance, which is a reason to treat them as a check rather than as a more conservative replacement for the NAIC-clustered errors in the main text.

Few effective clusters. The same concentration limits what either clustering can deliver. Because covered lives are concentrated in a handful of parents, a single cluster accounts for most of the variance of the estimate under both NAIC and parent clustering, so the effective number of clusters is far below the nominal count, and in the premium specification it is close to two. Asymptotic cluster-robust inference, and small-sample corrections such as the wild cluster bootstrap, are unreliable at that scale.

Pre-trends. One verdict changes. Under parent clustering the joint pre-trend test for deadpooling closers' profit rejects at the five percent level in Column 3, and the loss ratio's Column 3 test passes only narrowly. Deadpooling closers' profit therefore passes the pre-trend test in every column of Table 2, but not in the fully adjusted column once shocks are allowed to be shared across a parent's subsidiaries; the loss ratio passes in every column under either clustering.

P.4 Estimator Choice

The closure estimates in Section 7.1 use `csdid`'s `drimp` estimator rather than its default, `dripw`. This appendix reports the results both ways. The headline is that our findings are robust to the choice (the sign and order of magnitude of every estimate survive) but we prefer `drimp` because `dripw` discards a large share of the sample.

P.5 How the two estimators differ

Both are doubly-robust difference-in-differences estimators (Sant'Anna and Zhao 2020): each combines an outcome-evolution model with a propensity-score model for the probability of treatment, and is consistent if either one is correct. They differ only in how that propensity score is estimated.

`dripw` fits the propensity score by ordinary logit maximum likelihood, choosing $\hat{\gamma}$ to maximise the likelihood of the observed treatment assignment, and then forms inverse-probability weights from the fitted $\hat{p}(X) = \Lambda(X'\hat{\gamma})$. Balance across the covariates is a by-product: nothing in the objective requires it.

`drimp` instead uses *inverse probability tilting* (Graham, Campos De Xavier Pinto, and Egel 2012), which

Table A14. Table 2 with Parent-Company-Clustered Standard Errors

	(1)	(2)	(3)	Pre-Closure Means
Panel A: Per-Person Premiums (2025 $)				
Closure (deadpooling plans)	\$1,116***	\$1,049***	\$1,005***	\$2,347
	(187)	(191)	(198)	
Panel B: Per-Person Claims (2025 $)				
Closure (deadpooling plans)	\$724***	\$676***	\$606***	\$1,821
	(106)	(117)	(125)	
Panel C: Per-Person Profits (2025 $)				
Closure (deadpooling plans)	\$392***	\$373***	\$398***	\$526
	(87)	(83)	(77)	
Panel D: Loss Ratio (claims / premiums)				
Closure (deadpooling plans)	-0.035**	-0.038***	-0.056***	0.795
	(0.016)	(0.013)	(0.011)	
State controls		X	X	
Plan type controls			X	
N (plan-block-years, deadpooling only)	111,097	111,097	111,097	
Unique blocks	12,478	12,478	12,478	
Subsidiaries	291	291	291	
Parent companies	207	207	207	

Notes: Identical to Table 2 in sample, weighting, covariates, estimator (`drimp`) and base period (`long2`); point estimates are therefore the same. Standard errors in parentheses are clustered at the parent company, with each block assigned the parent group under which it carried the most covered lives over its life. "Parent companies" counts every parent group that appears in the arm's sample in any year, which exceeds the number of modal-parent clusters. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

chooses $\hat{\gamma}$ to solve the moment condition

$$\sum_i (1 - D_i)\, \exp\left(X_i'\hat{\gamma}\right) X_i \;=\; \sum_i D_i\, X_i, \tag{22}$$

so the reweighted control group matches the treated group's covariate means *exactly*, by construction. Balance is the objective rather than a consequence.

The practical difference appears when a covariate nearly separates treatment from control. Consider the plan-letter dummies: Plans M and N did not exist before June 2010, so for a cohort whose comparison window sits entirely in 2007–2010 those dummies are identically zero among the treated. Logit responds to perfect separation by sending the coefficient to $\pm\infty$; the fitted propensity approaches 0 or 1, the inverse-probability weights diverge, and the cell is dropped. The tilting condition (22) has no such failure mode, because it asks only that reweighted means agree, which remains solvable. The same mechanism explains why `dripw`'s standard errors are several times larger in every covariate-adjusted specification while being *identical* to `drimp`'s when no covariates are included—with no propensity model to fit, the two estimators coincide exactly.

P.6 What this costs in sample

Because whole cohort-period cells are dropped rather than down-weighted, the loss is concentrated in the early cohorts: under the fully-adjusted specification, `dripw` discards every cell whose comparison window touches 2007–2010.

We therefore do not adopt `dripw` as the main specification: it answers a question about a later, smaller panel than the one we observe. Reported alongside, it leaves the substance unchanged. On the deadpooling arm of Table 2, `dripw` returns a premium effect of $1,362 against `drimp`'s $1,005, and a profit effect of $548 against $398—larger under the default estimator, as the weight instability above would predict, but the same sign and the same order of magnitude.

The pre-trend diagnostics deserve a word of caution, because they run the other way and it is tempting to read them backwards. Under `dripw` the premium pre-trend test returns $p = 0.067$, against 0.004 under `drimp`: the default estimator appears to pass where our preferred one fails. That is not cleaner identification. The same inflated variance that widens `dripw`'s confidence intervals also widens the covariance the Wald statistic divides by, so the test loses power and fails to reject a violation that is present either way. A diagnostic that improves because the estimator became noisier is not evidence in the estimator's favour. The loss ratio survives under both (0.260 and 0.619), which is the outcome we lean on regardless.

The estimator choice therefore moves precision and sample, not conclusions.

P.7 The Two-Way Fixed-Effects Analogue

This appendix re-estimates the closure effect two ways that the main text does not use, and reports whether they agree with it. The first is the conventional two-way fixed-effects analogue, run with year, state, plan-type and plan fixed effects added in turn. It is not an independent test of identification (with staggered timing, TWFE weights some 2×2 comparisons negatively (Goodman-Bacon 2021)) so it is reported only to show that the result is not an artifact of the Callaway–Sant'Anna machinery. It agrees with the main-text magnitudes and is stable as the fixed effects are added.

Table A15 reports the before-and-after-closure comparison for premiums, claims, and profits, with never-closed plans as the control group, progressively adding year, state, plan-type, and plan fixed effects across columns. The estimates agree with the main-text magnitudes.

Community-rated blocks. We also estimated the closure effect within community-rated blocks, whose premiums cannot vary with age. Community rating coincides with other switching protections too often for those estimates to be informative: the comparison is underpowered, so we do not report it.

P.8 The Quoted-Price Effect Under Alternative Age Weightings

The quoted-price index in Figure 8 weights ages 65 to 85 by the MCBS age distribution of Medigap holders, so it answers what closure does to the price faced by the age mix that actually holds these

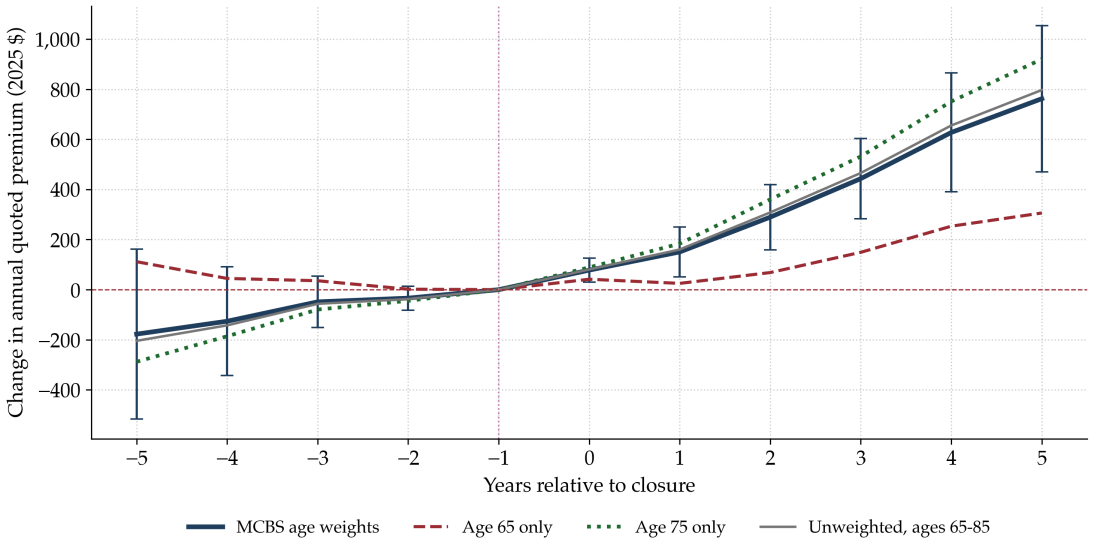

Table A15. Premiums and Profits Rise After Closure in Every Fixed-Effects Specification

	(1)	(2)	(3)	(4)	(5)	Mean before closure
Panel A: Per-Person Premiums (2025 $)						
	$764.37***	$799.01***	$898.41***	$590.03***	$482.55***	$2,615
	(96.76)	(111.41)	(109.75)	(120.87)	(119.97)	
Panel B: Per-Person Claims (2025 $)						
	$483.42***	$507.95***	$582.35***	$361.52***	$347.90***	$2,035
	(69.68)	(77.33)	(73.19)	(83.15)	(84.19)	
Panel C: Per-Person Profit (2025 $)						
	$280.96***	$291.06***	$316.06***	$228.50***	$134.66***	$580
	(39.97)	(43.64)	(39.82)	(40.83)	(41.95)	
Year FE		X	X	X	X	
State FE			X	X	X	
Plan Type FE				X	X	
Plan ID FE					X	
N (Life-Years)	174,112,756	174,112,756	174,112,756	174,112,756	174,112,754	
N (Plan-Years)	214,895	214,895	214,895	214,895	214,893	

Notes: All regressions are two-way fixed-effects specifications weighted by total lives, with never-closed plans as the control group and standard errors clustered at the NAIC insurer level. All monetary units are per enrollee in 2025 dollars. Standard errors are in parentheses, and stars denote statistical significance: * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. The result is that premiums and profits rise after closure and the estimates are stable as year, state, plan-type, and plan fixed effects are added, so the increase is not an artifact of which plans close, where, or when. See the text above for why this is a robustness exhibit rather than the paper's preferred estimator.

policies. That weighting is a choice, and Figure A13 shows what the alternatives would give: the price at a single age, 65 or 75, and a flat average over the whole 65–85 range. The four series are the same estimation on the same sample and differ only in how the age cells are combined, so any difference between them is the weighting and nothing else.

Figure A13. The Quoted-Price Closure Effect Under Four Age Weightings

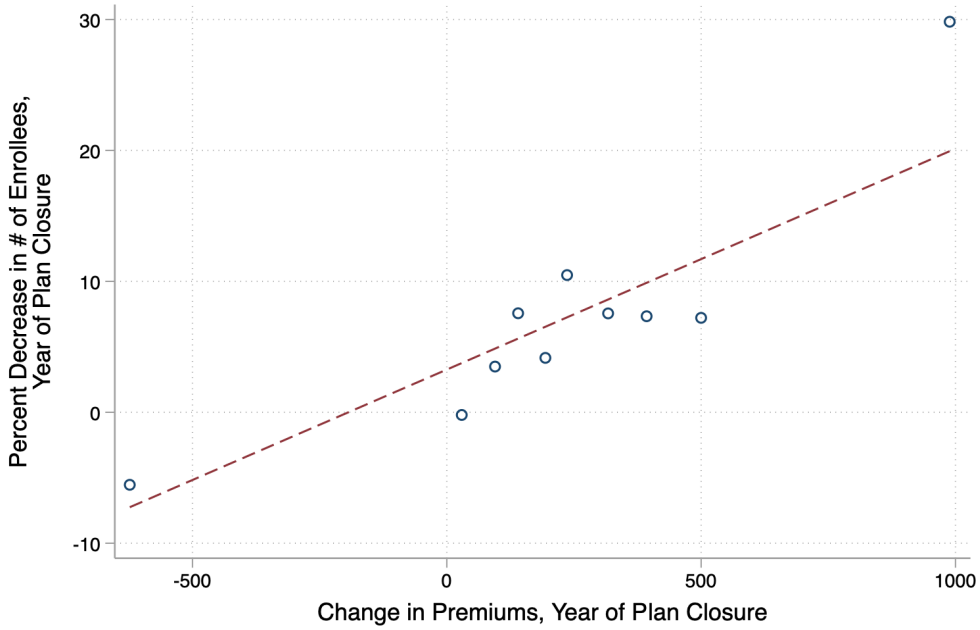

Notes: Callaway–Sant'Anna ATT of plan closure by event time on the CSG quoted price, normalized to zero at $t = -1$, on the specification of Figure 8. Navy is the MCBS-weighted index reported there. The other three series reweight the same age cells: the quoted price at age 65 alone, at age 75 alone, and a flat unweighted average over ages 65 to 85. All are annual rates in January 2025 dollars for a non-tobacco applicant, and all are the female quote, which is the gender the CSG age profile is built on. Confidence intervals are drawn for the MCBS series only, and the single-age series are offset horizontally by a tenth of a year, to keep the figure readable. Joint pre-trend tests (leads $t-6$ to $t-2$, $t-1$ the base period): no pre-trend test in this figure is significant at the 5% level (the MCBS-weighted index, $p = 0.185$; the equal-weight index, $p = 0.152$).

Q Appendix: Enrollees Leave in Response to Premium Increases

A central premise of the deadpooling mechanism is that policyholders leave a closed block *because* they are charged rising premiums, not simply dying off or exiting at random. This appendix examines that premise directly. For each deadpooling block we measure first-year disenrollment as $1 - L_{t_c+1}/L_{t_c}$, where t_c is the year the block closes to new enrollment and L is enrollment, so the window runs from the closed pool forward one year. We relate it to three measures of the price policyholders face over the same window: the markup *level* (premium/claims), premium *growth* ($p_{t_c+1}/p_{t_c} - 1$), and the absolute premium *increase* in dollars. All statistics are enrollment-weighted and variables are winsorized at the 1st and 99th percentiles; fitted lines are OLS and each is annotated with its equation. The sample is the 2,356 deadpooling closures with observed enrollment and premiums in both the closure year and the following year.

Figure A14 gives the aggregate version of the price relationship, binning closing plans into deciles of premium change and plotting the associated enrollment loss; it is the figure the main text points to when it notes that beneficiaries respond to price. The block-level regressions that follow decompose that binned pattern by the specific price measure enrollees face.

Figure A14. Larger Premium Increases Are Associated with Larger Enrollment Losses

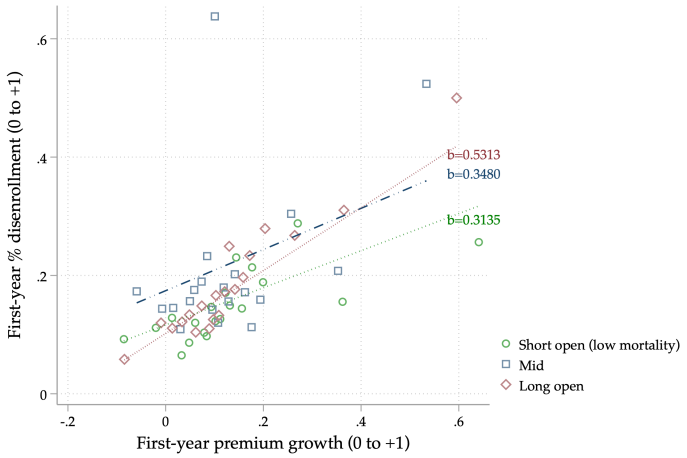

Notes: This plot scatters deciles of the one-year change in per-enrollee premium over the closure year (January 2025 dollars) against the percent decrease in enrollees each plan experiences over the same year. The window is one year to limit the role of mortality. Deciles are defined using total lives as weights. Closures are defined based on calendar year, so a closed plan gaining lives (as displayed in the rightmost point) would have made those gains in the part of the year before closure. Closure dates cluster heavily on a semiannual convention: among the 7,717 plans with a recorded closure date, 30% close effective the end of May or June 1 and 26% the end of December or January 1, so 56% fall on one of these two dates. The upward slope is consistent with enrollees responding to price when deciding whether to disenroll: plans in the top decile of premium increases (about $1,000 a year) lose roughly 30% of their enrollment. The relationship is descriptive rather than causal (premium growth and disenrollment are jointly determined, since the departure of healthier members itself worsens the pool and pushes premiums up) and which margin leavers exit to (another Medigap, Medicare Advantage, or no supplemental coverage) is not observable in these data.

Disenrollment tracks how much the premium rises. Each additional $100 of first-year premium increase is associated with 1.2 percentage points more disenrollment (Figure A14); in percentage terms, a block whose premium rises ten percentage points faster loses roughly an additional 2.7 percentage points of its enrollment in the first year (pooled slope 0.27, s.e. 0.07; 0.36 with state and block-age fixed effects). The markup *level* (premium over claims), which enrollees never observe, has no relationship with exit (slope 0.001, s.e. 0.008).

Ruling out mortality. The response is not an artifact of sicker, older pools dying off. First, the premium-growth relationship holds within strata of two separate proxies for a block's mortality risk. Splitting on block age (years since the block's filed approval, a proxy for the pool's age) the slope is positive in all three terciles (0.31, 0.35, and 0.53) and significant in the youngest, lowest-mortality blocks ($p = 0.002$) as well as the oldest; the middle tercile is imprecisely estimated (standard error 0.22) rather than flat (Figure A15). Splitting instead on pre-closure per-person claims (a proxy for pool health) the slope is 0.35 in the lowest-claims/low-mortality quartile and 0.44 in the highest-claims quartile (Figure A16). Second, a direct accounting bounds the mortality contribution: applying Social Security period life-table death rates (Social Security Administration 2024) to the MCBS age mix of the Medigap population implies expected annual mortality of about 4.3%, against mean first-year disenrollment of 17.4%, so roughly 75% of first-year exits are not attributable to death (and 43% even under a deliberately high 10% mortality ceiling). Random attrition is likewise inconsistent with the evidence, since idiosyncratic exit would not co-move with premium growth.

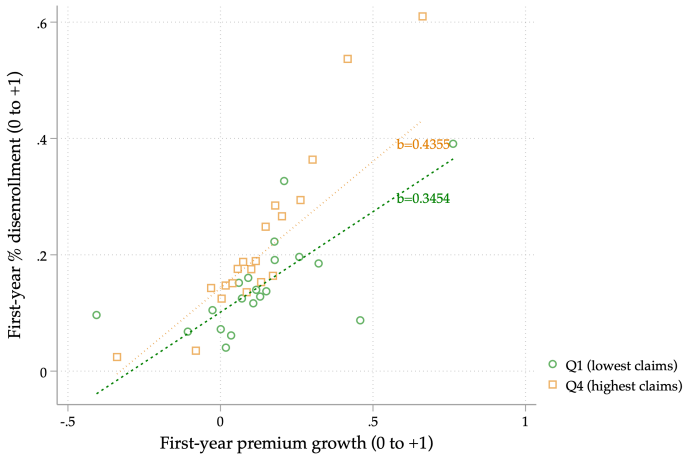

Figure A15. The Premium Response Holds Even in the Youngest, Lowest-Mortality Blocks

Notes: Binned scatter with OLS fits by tercile of block age, a proxy for pool age and hence mortality risk. Block age is dated from the block's filed approval date, not from its first year in the panel: the panel begins in 2006, so dating from it would floor every earlier-approved block at 2006 and understate the age of the 40.4% of the 2,203 blocks here whose approval predates the panel, pushing genuinely old pools into the youngest tercile. Enrollment-weighted. The slope is positive in all three terciles (0.31, 0.35, 0.53) and significant in the youngest ($p = 0.002$) and the oldest; the middle tercile is imprecisely estimated (standard error 0.22) rather than flat. The response holds among the youngest, lowest-mortality blocks, so the disenrollment response cannot be death in disguise.

Cost pass-through versus a price response. A remaining concern is that premiums might be rising only to track the block's own worsening costs, so that "response to premiums" is really a response to

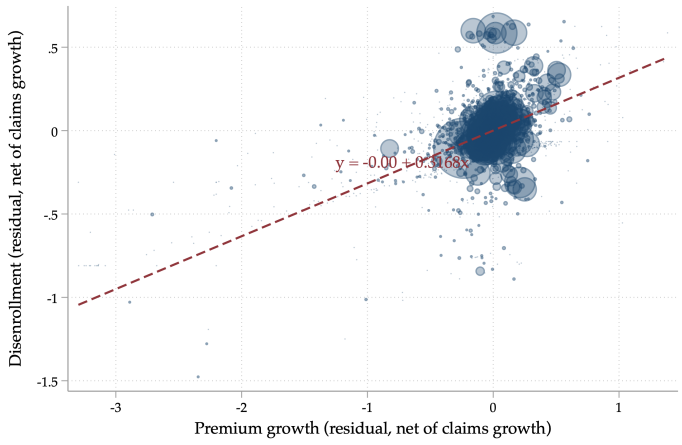

Figure A16. The Premium Response Holds in the Healthiest Blocks

Notes: Binned scatter with OLS fits for the extreme quartiles of pre-closure per-person claims, a second proxy for pool health and mortality risk. Enrollment-weighted. The response is present among the healthiest blocks as well as the sickest: the slope is 0.35 (s.e. 0.10) in the lowest-claims quartile against 0.44 (s.e. 0.06) in the highest. The two interior quartiles are not plotted because they are uninformative rather than genuinely flat: the second quartile's slope is 0.12 (s.e. 0.10) and the third's is 0.12 (s.e. 0.48), the latter estimated so imprecisely that its confidence interval spans both extremes. That the response survives where mortality risk is lowest is what a mortality explanation cannot produce.

rising claims. Controlling for contemporaneous claims growth, however, the premium-growth coefficient survives and if anything strengthens (to 0.32, $p < 0.001$), while claims growth on its own carries no independent relationship with exit (-0.06, not significant). Figure A17 plots the partialled-out (Frisch–Waugh) relationship: disenrollment and premium growth after each is purged of its claims-growth component. Policyholders leave when the premium rises, not merely when the underlying cost of their pool rises.

Figure A17. Enrollees Leave When the Premium Rises, Not When Costs Rise

Notes: Frisch–Waugh residualized scatter: first-year disenrollment and first-year premium growth are each regressed on first-year claims growth, and the residuals plotted against one another. The slope (0.32) equals the premium-growth coefficient in the multivariate regression that also includes claims growth. Enrollment-weighted; marker size proportional to enrollment. Controlling for the block's own claims growth, the premium-growth coefficient survives and strengthens to 0.32 ($p < 0.001$), while claims growth carries no independent relationship with exit (-0.06, insignificant). The response is to the price, not to the underlying cost of the pool.

The two coefficients are worth reading together, because each rules out a different alternative and only the pair settles the question. That premium growth predicts exit *holding claims fixed* rules out the health

story: if enrollees were leaving because they were getting sicker or dying, the claims term would carry that and the premium term would not survive its inclusion. It does survive, and strengthens. That claims growth carries no independent relationship *holding premiums fixed* rules out the converse: rising costs do not move people except through the price they are charged. So price is the operative margin, and the exit we observe is a behavioral response to being repriced rather than a mechanical consequence of a deteriorating pool. This is a statement about the *margin* people respond to, not a claim that selection is absent—who leaves is still selected on health, which is the composition effect the closed-block claims decomposition addresses separately.

Taken together, these patterns show that disenrollment from deadpooling blocks tracks the premium *increase* (in percentage or dollar terms) rather than the premium level, that this holds within low-mortality subpopulations and after netting out expected deaths, and that it reflects the premium itself rather than cost pass-through. We interpret this as descriptive evidence consistent with a demand response and inconsistent with the pure-mortality and pure-attrition alternatives. It is not a causal estimate: premium growth and voluntary exit are jointly determined, since the departure of healthier members itself worsens the pool and pushes premiums up. The identified price elasticity underlying these correlations is estimated structurally in Section 8.

R Appendix: Enrollees Place Little Value on Their Insurer

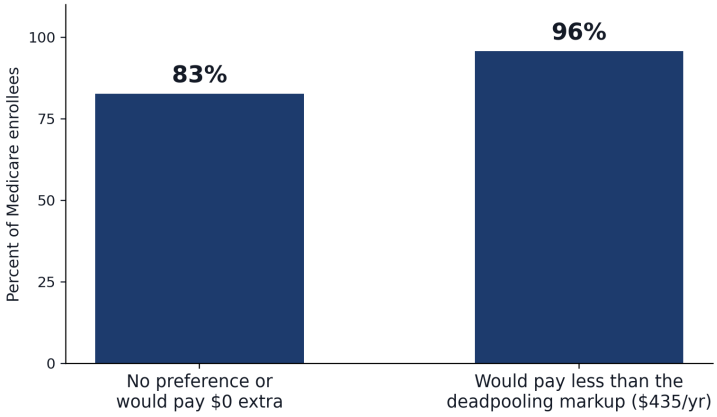

If enrollees valued staying with a particular insurer, the brand could discipline the repricing of a closed block. They do not. Our Understanding America Study module asks Medicare enrollees whether it would matter which company insures them and, if so, how much more they would pay each year to have a plan issued by their preferred company rather than identical coverage from the cheapest seller. Among 1,849 respondents (survey-weighted), 83% have no preferred insurer or would pay nothing extra to stay with it (66% have no preference; 16% have one but would pay nothing). 96% would pay less a year than the $435 premium rise a deadpooled block imposes, and 96% less than the $398 profit rise. Figure A18 shows the distribution. Almost no one would pay a brand premium anywhere near the repricing.

S Appendix: What Lock-In Buys: Stable Pools and Who Enters Them

Everything above prices what lock-in costs. It is worth asking what it buys. The defense of underwriting is that it keeps risk pools intact: if the healthy cannot be skimmed away and the sick cannot pile in, a block should be able to hold its price steady and stay open. This subsection tests that claim on its own terms, and finds that it is partly true—which is the strongest case the practice has.

How many pools are actually stable? Call a pool *stable* if it never closes, stays open at least five years, and never raises its price by more than a given amount from one year to the next. Measured on *realized* per-enrollee premiums, almost none is: only 1.5% of enrollees sit in a pool that clears a ten percent bar.

Figure A18. Willingness to Pay to Stay with a Preferred Insurer

Notes: Understanding America Study, Medicare enrollees, survey weights; N = 1,849. Respondents with no preferred insurer count as zero; 23 with a preference but no answer are dropped. The right bar compares each answer with the deadpooling closure premium ATT (Table 2, column 3).

That figure is misleading, and the reason matters. Realized per-enrollee premium is total premium over covered lives, so it moves with who is enrolled as much as with what is charged—a block whose healthy members leave posts a "spike" none of its remaining enrollees was billed. The quoted rates price the same hypothetical applicant every year, so composition cannot move them, and they are the right instrument here for exactly the reason they were in Section 7.5.

On quoted rates the picture reverses. Of 12,301 blocks in the CSG panel, 4,083 never close and stay open at least five years, and among all life-years 15.7% sit in a pool whose rate for a 65-year-old never rises more than ten percent in a year; at 75 the figure is 16.8%. Tighten the bar to five percent (below ordinary medical trend) and stability becomes rare again, 2.0% and 2.2%. So most pools do not reprice violently. The instability the realized series shows is overwhelmingly *composition*, not repricing, and that is itself a finding: the per-enrollee premium series that the literature typically observes overstates how much price risk an enrollee bears.

Stability is highest where switching is most restricted. Splitting by regime, 18.5% of life-years in states with no switching protections sit in a stable pool at age 65, against 5.4% under an annual switching window and 2.5% under open enrollment; at 75 the gap is wider still (19.8% against 2.5%). The ordering runs the way the stability defense predicts, and it is the one cut in this paper where restricted switching looks good.

Who enters a new block, and where. The mechanism behind that ordering is visible at entry. A block opening in a state where underwriting binds can screen its applicants; one opening where anyone may buy in annually cannot. We score every block that opens after the panel begins on its first-year per-enrollee claims, relative to the lives-weighted claims of every block in the same state, plan letter and year—a within-cell benchmark, so a state's cost level cannot drive the comparison. Across 12,255 new blocks, the median entrant opens at 0.22 of incumbent claims where there are no protections and 0.26 under an annual switching window, but 0.43 under open enrollment; weighting by the entrant's own

enrollment the contrast is 0.51 and 0.39 against 0.90. Where buyers can enter without underwriting, a fresh block opens with a pool that looks like the market; where they cannot, it opens at half the market's risk or better.

Reading this against the rest of the paper. The same screening that makes deadpooling profitable—the underwriting that keeps a closed block's sick from leaving —also keeps a new block's pool from filling with them. Lock-in is not doing nothing. It buys measurably steadier prices and measurably cleaner entry, and a market design that removes it should expect to give some of that up. What this paper documents is the price of that purchase: the same mechanism hands the incumbent insurer a captive pool to reprice, and Sections 7.1 through 7.2 measure what it extracts from it. The defense of lock-in is real but partial, and the question a regulator faces is not whether it works but whether it is worth what it costs.

Three caveats travel with these numbers. The open-enrollment cell rests on 188 entering blocks in three states, so it is indicative rather than precise. The quoted-rate panel runs 2014–2025, a shorter window than the claims panel, so the five-year screen is judged over twelve years rather than twenty. And the entry ratio measures a block's *ability to screen*, not welfare: a new block that cannot skim is evidence that a protection binds, not that the market is worse off for it.

T Appendix: Is the Practice More Intense in Some Regimes Than Others?

The closure event study of Section 7.1 is run on states without switching protections, which is where the mechanism should operate. Running the same specification separately by regulatory regime asks whether that restriction is doing work, or whether closure looks the same everywhere. It is doing work.

Table A16 reports the five-year ATT on each outcome for each regime. The contrast that identifies the question is between the forty-three states with no switching protections and the eight with an annual switching window. Where enrollees cannot leave, closure raises the per-person premium by $745 five years out and per-person claims by $423, both significant, and the loss ratio falls by -0.054. Where an annual window exists, none of those three is distinguishable from zero: the premium effect is $239 with an interval spanning zero, claims are $4, and the loss ratio moves -0.036. The practice is not merely more common where switching is restricted, as Figure 13 shows; conditional on a closure happening, it is also more profitable.

Enrollment behaves differently from all four, and the difference is the point. Measured in logs, so that it is comparable across regimes holding very different block sizes, enrollment in a closed block falls by -50.2% within five years where switching is restricted and by -49.5% where a switching window exists. Those are the same number. Roughly half the block leaves either way, and the regulatory regime does not change how many go. What changes is who is left and what they are charged: the remaining pool is measurably sicker only where enrollees cannot leave, and only there is it repriced. The regime does not

govern the volume of exit so much as its composition.

The third regime, the three states operating a continuously open market, is reported for completeness rather than as a third comparison. Connecticut, Maine and New York are the states whose pre-existing rules make them unusable as controls in Section 8.2, and with three treated clusters the confidence intervals there should be read as indicative. Its point estimates run in the same direction on profit and the loss ratio; we would not rest anything on them.

Table A16. Closure Effects Are Concentrated Where Enrollees Cannot Switch

Five-year ATT	No switching protections (43 states)	Annual switching window (8 states)	Continuously open market (3 states)
CSG quoted-price index ($)	779	373	—
Per-person premium ($)	745	239	209
Per-person claims ($)	423	4	-375
Per-person profit ($)	322	235	584
Loss ratio	-0.054	-0.036	-0.121
Enrollment (% change)	-50.2	-49.5	-35.6

Notes: The first row is the ATT on the CSG quoted-price index—a fixed (Laspeyres) basket over ages 65–85 weighted by the MCBS age distribution of Medigap holders, extended past the end of a closed block's quotes by the closed-block rate increases the carrier filed—estimated on the same specification with control block-years restricted to blocks quoted in their own right that year. Because a fixed basket cannot move with the pool, it separates repricing from composition within each regime; the row below it is the realized per-enrollee premium. The by-regime cells are thin and the continuously-open column rests on three states: on the quoted-price index only 170 treated block-years survive there and no five-year cell is estimated at all, which is why that entry is an em-dash rather than a number. Read the other two columns as the comparison. Callaway–Sant'Anna ATT at event time $+5$, by state regulatory regime, from the specification of Figure 3 estimated separately within each regime. Never-closing, never-deadpooling blocks are the control group in each. Dollar outcomes are per enrollee in 2025 dollars and are enrollment-weighted. Enrollment is the ATT on *log* enrollees, reported as a percentage change: mean pre-closure block size differs across regimes (roughly 1,156, 987 and 538 lives in the open-market, annual-window and no-protection regimes), so a level effect is not comparable across them, and normalising a level effect by those means reverses the ordering of the second and third columns. The three-state column rests on three treated clusters and its intervals are indicative rather than well-sized; those states are excluded as controls elsewhere in this section for the same pre-existing-rules reason.

The premium series in each of those figures is a realized per-enrollee amount, so it carries pool composition as well as price. Figures A19–A21 give the quoted-price counterpart regime by regime: the same closure event study run on a fixed basket of ages, which composition cannot move. The ordering across regimes is the one the lock-in mechanism predicts, and reading each against the premium panel beside it separates what the carrier charged from who was left to charge it to.

U Model Details

U.1 Market Structure

The market consists of $F = 37$ parent insurance companies, each operating across $S = 5$ states and offering $L = 3$ standardized plan tiers—three representative plans calibrated to aggregate market moments rather than models of Plans F, G, and N specifically. Each company–state–plan-tier triple defines a *block*: a pool of enrollees sharing a community-rated premium. Blocks are indexed by $b \in \mathcal{B}$. There are thus up to $F \times S \times L = 555$ potential blocks active at any time, though not all are open. Each block b is characterized by its current premium P_b, its open/closed status, its age, and its risk-pool composition. Community rating requires all enrollees in a block to pay the same annual premium,

Figure A19. The Quoted Price After Closure Where Enrollees Have No Route Out (43 States)

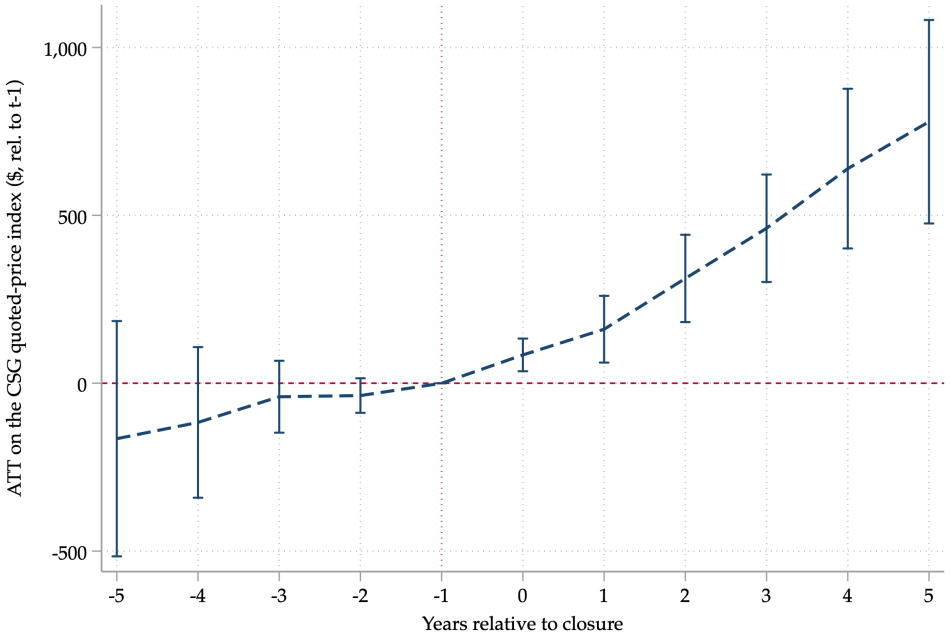

Figure A20. The Quoted Price After Closure Where an Annual Switching Window Exists (8 States)

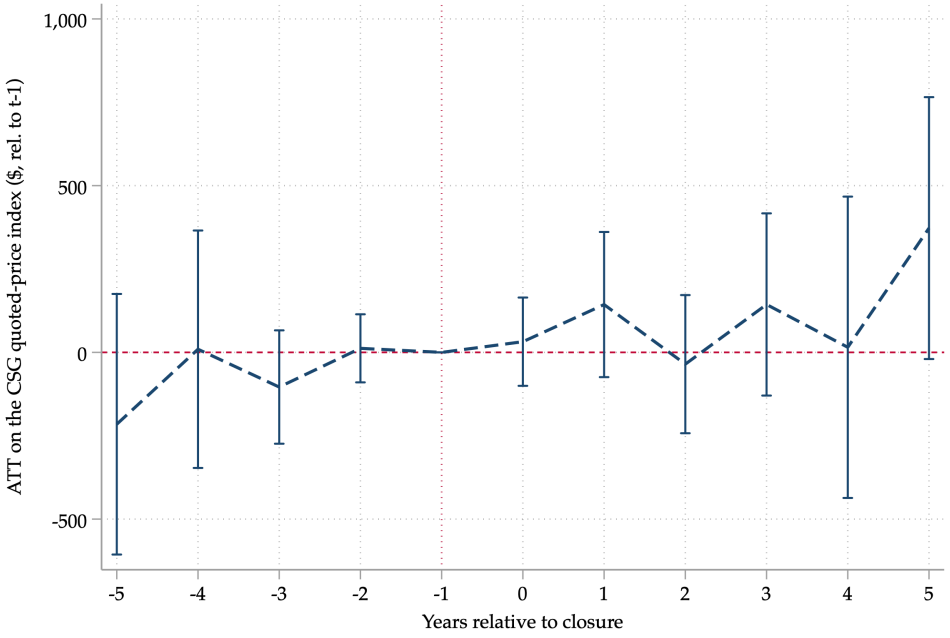

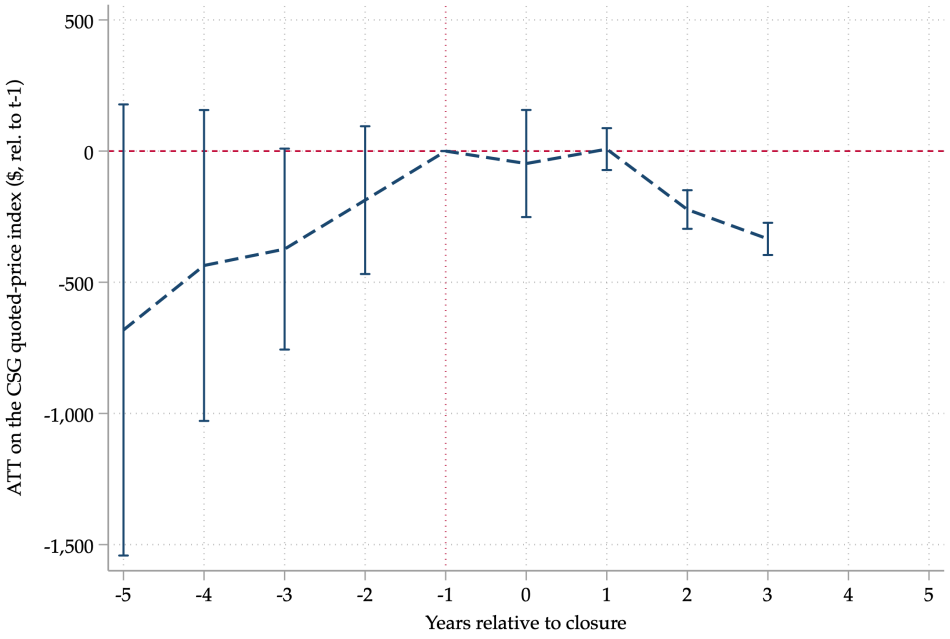

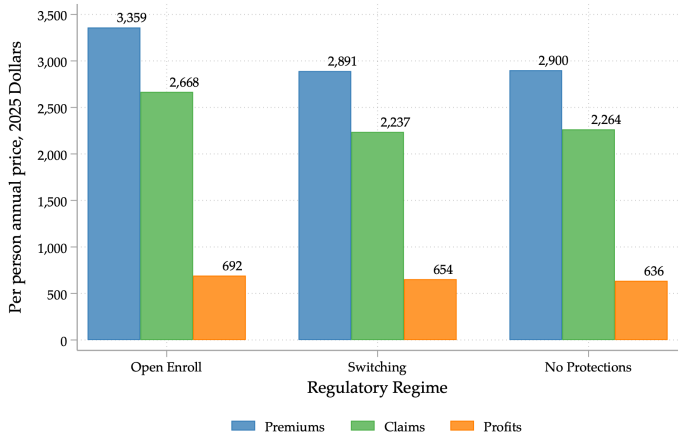

Figure A21. The Quoted Price After Closure in the Three Continuously Open States (CT, ME, NY)

Notes: Callaway–Sant'Anna ATT of plan closure by event time on the CSG quoted-price index, estimated separately within each switching regime and normalized to the year before closure. The index is a fixed (Laspeyres) basket over ages 65–85 weighted by the MCBS age distribution of Medigap holders, in annual 2025 dollars, extended past the end of a closed block's quotes by the closed-block rate increases the carrier filed with the state. Specification, control group, estimator, base period, weighting and clustering match Figure 3; control block-years are restricted to blocks quoted in their own right that year, so no control price is imputed from a filing. These are the same estimates as the quoted-price row of Table A16. The regime cells are thin (the continuously-open figure rests on three states) so the intervals are indicative rather than well-sized, and all CSG quotes are the female non-tobacco rate. Joint pre-trend tests (leads $t-6$ to $t-2$, $t-1$ the base period), at the 5% level: where enrollees have no route out, no test is significant (the quoted-price index $p = 0.088$); where an annual switching window exists, the test rejects for the quoted-price index $p = 0.000$; in the open states, the test rejects for the quoted-price index $p = 0.000$. All other pre-trend tests in these figures are not significant at the 5% level.

Figure A22. Premiums, Claims, and Profits Are Nearly Identical Across Switching Regimes

Notes: This plot is weighted by total lives and is calculated on block-years through 2020, matching the five-year look-forward window used to classify deadpooling elsewhere in the paper and the sample of Figure 13 beside it. Differences between switching-regime and unprotected states are essentially zero on all three measures, which is inconsistent with the claim that switching rules generate substantial adverse selection. Premiums and claims are higher in open-enrollment states, which is consistent with selection into the market under those rules—though as averages these cannot rule out offsetting reallocations within the market.

regardless of health status or age. New enrollees may only enter open blocks.

U.2 Consumer Demographics and Health

U.2.1 Aging and Mortality

Each consumer i enters the model at age 65 and ages one year per period. Mortality depends on both age and health status:

$$\mu(a, h) = \mu_0^h \times m_\mu(a), \tag{23}$$

where μ_0^h is the age-65 baseline mortality rate for health state h and $m_\mu(a)$ is an age multiplier calibrated from MCBS and applied via linear interpolation between anchor ages. The baseline rates are $\mu_0^{\text{healthy}} = 0.015$, $\mu_0^{\text{moderate}} = 0.030$, and $\mu_0^{\text{sick}} = 0.080$. The moderate baseline is calibrated from self-assessed health relative-risk estimates in the MCBS: beneficiaries reporting "good" health have approximately twice the annual mortality of those reporting "excellent" or "very good" health (Lee et al. 2003), yielding $0.015 \times 2 = 0.030$. The mortality multipliers are $m_\mu(65) = 1.000$, $m_\mu(75) = 2.500$, and $m_\mu(85) = 6.667$, with linear extrapolation beyond age 85. These come from the *SSA 2021 period life table* (combined male and female, the arithmetic mean of q_x within each age bin), not from the MCBS: the MCBS public-use file records no death or vital status, so it cannot identify mortality at all. Age multipliers for expected claims are a separate matter and *are* from the MCBS, applied via linear interpolation between anchor ages, with values of 1.000 at age 65, 1.204 at age 75, and 1.299 at age 85. They are ratios of the mean count of reported conditions by age group rather than of dollar spending, since the public-use file carries health-burden outcomes and not claims; the condition-count ratio is a proxy for how costs rise with age, and a conservative one, as counts understate the convexity of spending in age. Beyond age 85, both multipliers are extrapolated linearly using the slope of the 75–85 interval.

U.2.2 Health States and Transitions

Each consumer occupies one of three health states: *healthy* ($h = H$), *moderate* ($h = M$), or *sick* ($h = S$). Annual medical claims are drawn from a normal distribution truncated at zero. The age-adjusted mean claims are $\bar{c}_H = \$1{,}050$, $\bar{c}_M = \$1{,}600$, and $\bar{c}_S = \$2{,}900$, with coefficients of variation $\text{CV}_H = 2.4$, $\text{CV}_M = 2.0$, and $\text{CV}_S = 1.8$ respectively. The relative ratios across states (1.00 : 1.54 : 2.77) are calibrated from the MCBS Cost Supplement PUF (2023), and the overall level is set so that the enrollment-weighted average claims matches the NAIC market average of \$2,255 per enrollee. New 65-year-olds are drawn healthy, moderate, or sick with probabilities 0.80, 0.15, and 0.05. That split is an assumption rather than an estimate: it is not calibrated to any moment and no MCBS analogue pins it, and it matters because it sets the starting composition of every fresh block and hence the level of the teaser price a successor can offer. The implied entry-cohort claims level, $0.80(1{,}050) + 0.15(1{,}600) + 0.05(2{,}900) \approx \$1{,}225$, is the figure the model uses for a newly opened pool.[21]

21. The MCBS measure used is `PAMTALPR` (total private insurance payments), restricted to beneficiaries on traditional Medicare with no Medicaid and positive private insurance payments. CV estimates by chronic-condition group (0–1, 2–3, 4+ conditions) are

Health transitions follow a first-order Markov process. Health can only worsen:

$$\Pr(h_{t+1} = M \mid h_t = H, a) = p^0_{HM} + \delta \cdot (a - 65), \tag{24}$$

$$\Pr(h_{t+1} = S \mid h_t = M, a) = p^0_{MS} + \delta \cdot (a - 65), \tag{25}$$

Here $h_t \in \{H, M, S\}$ is the consumer's health state in year t (healthy, moderate, or sick) and a is their age. The baseline one-year transition probabilities are $p^0_{HM} = 0.06$ from healthy to moderate and $p^0_{MS} = 0.09$ from moderate to sick, and $\delta = 0.003$ is the amount by which each rises per year of age above 65. Consumers enter at age 65 and never earlier, so $a - 65 \geq 0$ always and no truncation at zero is needed. Once a consumer reaches the sick state they remain there permanently, so S is absorbing.

U.3 Consumer Demand

U.3.1 Willingness to Pay

A consumer's WTP for Medigap coverage is the certainty equivalent of the claims the coverage absorbs, computed by forward-simulating a 20-year Markov chain from the consumer's current health state. Let $\pi_\tau(h')$ denote the probability of being alive and in health state h' at horizon τ, and $S_\tau = \sum_{h'} \pi_\tau(h')$ the survival probability. The WTP center is the survival-weighted average annual claims plus a CARA risk premium proportional to the survival-weighted average annual claims variance:

$$\bar{v}_h = \frac{\sum_{\tau=1}^{T} \sum_{h'} \pi_\tau(h')\, \bar{c}_{h'} m_c(a_\tau)}{\sum_{\tau=1}^{T} S_\tau} + \frac{\rho}{2} \cdot \frac{\sum_{\tau=1}^{T} \sum_{h'} \pi_\tau(h') \left(\mathrm{CV}_{h'}\, \bar{c}_{h'} m_c(a_\tau)\right)^2}{\sum_{\tau=1}^{T} S_\tau}, \tag{26}$$

where $T = 20$ and ρ is the CARA absolute risk-aversion coefficient. Risk-averse consumers therefore value coverage above its expected cost; setting $\rho = 0$ recovers the actuarially-fair (expected-claims) WTP. With $\rho = 1 \times 10^{-4}$, this produces WTP centers of $\bar{v}_H = \$1{,}821$, $\bar{v}_M = \$2{,}716$, and $\bar{v}_S = \$3{,}580$ at age 65 (versus \$1,556, \$2,285, and \$3,199 at $\rho = 0$). Individual WTP is drawn from $\mathcal{N}(\bar{v}_{h_i},\ (\sigma_v \bar{v}_{h_i})^2)$ truncated to $[0, 4\bar{v}_{h_i}]$ with $\sigma_v = 0.40$, and redrawn each year as health evolves.

U.3.2 Price Sensitivity

Each consumer i is assigned a price-sensitivity index $\lambda_i \in [0, 1]$ drawn from Beta($\alpha \approx 0.60,\ \beta \approx 2.40$), parameterized with mean $\mu_\lambda = 0.20$ and standard deviation $\sigma_\lambda = 0.20$. This is a right-skewed distribution with density decreasing monotonically from the origin, placing most mass at low price-sensitivity values, consistent with UAS survey evidence that 68% of enrollees consulted only one agent and 73% have never switched. Price sensitivity is drawn once at birth and held fixed throughout a consumer's life.

2.43, 2.00, and 1.81 respectively.

U.3.3 Enrollment Decision

Each year, $N_{\text{new}} = 7{,}000$ new 65-year-olds enter the market and enroll in Medigap. Entrants are allocated across open blocks with probability inversely proportional to premium. New entrants face no underwriting—they have guaranteed issue at age 65. Underwriting applies only to mid-market switches and re-entry: $\rho_H = 0.95$, $\rho_M = 0.25$, $\rho_S = 0.05$, with an additional age penalty of 1 percentage point per year above 65.

U.3.4 Switching

Each period, enrolled consumers consider switching to a cheaper block. Consumer i shops with probability $\Pr(\text{shop}_i) = 0.20 \times \lambda_i$. Conditional on shopping, consumer i switches only if annual savings exceed a price-sensitivity-scaled threshold:

$$\text{switches} \iff P_{b_i} - P_b^{\min} \geq \frac{\bar{s}}{\lambda_i}, \tag{27}$$

where $\bar{s} = \$75$. The base shopping rate $p_s = 0.20$ and threshold $\bar{s} = \$75$ are calibrated jointly to reproduce the approximately 2% annual switching rate in the UAS survey. Switching also requires passing underwriting, which is where health enters the consumer's problem: a healthy applicant passes with probability 0.95, a moderate one with 0.25 and a sick one with 0.05, each falling a further point per year of age above 65, and the screen is waived inside a birthday-rule or guaranteed-issue window. Those probabilities are specified in the enrollment subsection above; a consumer who fails the screen stays where they are regardless of how large the saving would have been, which is the mechanism that makes the closed pool captive.

U.3.5 Exit and Re-entry

Consumers exit the Medigap market if premiums significantly exceed their WTP:

$$\Pr(\text{exit}_i) = \lambda_i \cdot \gamma^{\text{exit}} \cdot \max\left(0, \frac{P_{b_i} - v_i}{P_{b_i}}\right), \tag{28}$$

where $\gamma^{\text{exit}} = 0.15$ is the exit responsiveness, calibrated to match the 0.56% annual rate at which Medigap enrollees leave the market, measured directly in the UAS module. (Both figures were previously stated as 1.80 and 5.3%: the target was a stock share rather than the annual flow the model produces, and the responsiveness had been hand-set to match it.)

Why the exit response is linear. Equation (28) is linear in the proportional excess of premium over willingness to pay, so γ^{exit} scales every consumer's exit hazard by the same factor. That is a restriction, and it is the natural suspect for the one moment the model does not reproduce: post-closure retention is too high at every horizon, which is a statement about *who* leaves rather than *how many*. An enrollee whose premium has been marked up far above their WTP should leave much faster than one barely above it, and under a linear rule they do not.

We therefore estimated a generalized version, replacing the bracketed term in Equation (28) with its γ-th power and searching over $\gamma \in \{1, 1.5, 2\}$ jointly with the other calibrated parameters. The linear rule wins outright: minimized loss is 0.54 at $\gamma = 1$ against 0.70 at $\gamma = 1.5$ and 0.95 at $\gamma = 2$. Convexity does move retention in the intended direction—the five-year retention rate falls from 0.68 to 0.65 against a target of 0.54—but it suppresses exit everywhere the excess is small, which is most of the market, and the aggregate exit rate collapses from 0.0059 to 0.0031 against a target of 0.0056. The shape gained is bought at a larger cost in the level, and the objective rejects the trade. Values $\gamma < 1$ were not searched because they invert the mechanism, making the mildly repriced leave relatively more readily than the heavily repriced.

We read this as evidence that the retention shortfall is not reachable through the functional form of the exit margin. The remaining candidate is the other route out of a closed block (passing underwriting to switch carrier) which is governed by the acceptance probabilities rather than by Equation (28).

The retention shortfall is an underwriting margin, not an exit margin. We checked this directly, varying the acceptance probability for enrollees in the intermediate health state, ρ_M, while holding every other calibrated parameter at its fitted value. Retention responds to ρ_M far more than it responds to anything on the exit side: raising it from 0.25 to 0.55 moves the five-year retention rate from 0.68 to 0.64 against a target of 0.54, and more than halves the calibration loss. By comparison, freeing the exit responsiveness across an entire recalibration moved five-year retention by less than one percentage point, and the convex exit rule described above moved it the right way only by breaking the aggregate exit rate.

We do not adopt the higher value, for two reasons. The first is substantive and is the reason ρ_M was set to 0.25 in the first place: an enrollee in the intermediate health state is by construction sicker than a healthy one and should not pass underwriting at close to the healthy rate, whatever it does for the fit. A parameter that is identified by an assumption about who insurers accept should not be re-identified by a moment about how long pools drain. The second is that the response is not clean enough to fit on: it is non-monotone across the values we tried, with $\rho_M = 0.40$ fitting worse than either 0.25 or 0.55 on every retention horizon, which at two seeds per cell is consistent with simulation noise of the same order as the effect. Raising ρ_M also moves the carrier-switching rate further from the UAS figure, trading a validation moment against the targeted ones.

What the exercise does establish is where the limitation lies. The model retains trapped enrollees too long because too few of them can pass underwriting and leave, not because those who would rather drop coverage are insufficiently responsive to price. That is a sharper statement than "the model empties closed blocks too slowly", and it points at the one primitive in this part of the model that is assumed rather than estimated. Consumers who have exited can re-enter if premiums fall relative to their WTP:

$$\Pr(\text{reenter}_i) = \lambda_i \cdot \gamma^{\text{re}} \cdot \max\left(0, \frac{v_i - P_b^{\min}}{v_i}\right). \tag{29}$$

Re-entry requires passing underwriting; the re-entry responsiveness $\gamma^{\text{re}} = 0.50$ is calibrated separately to

match the approximately 1.6% annual re-entry rate in the UAS data. The exit and re-entry responsiveness parameters were re-calibrated jointly with the risk-averse WTP: because the risk premium raises WTP, fewer consumers exit and more re-enter at a given premium, so γ^{exit} rises and γ^{re} falls relative to a risk-neutral specification.

U.4 Insurer Pricing

Each block b sets a community-rated annual premium updated each year via exponential a markup over the prior year's claims, as in equation (19). Open plans use markup $m^{\text{nd}} = 1.24$, calibrated via the grid search and close to the large-company aggregate non-dp markup in the MSI data (1.239), implying a target loss ratio of $1/1.24 = 80.6\%$. Closed dp blocks charge a markup that ramps with years since closure—$m^{\text{nd}} + 0.02$ in the first year after closure, rising to $m^{\text{nd}} + 0.08$ (about 1.34) from the third year on—scaled by a calibrated multiplier on this schedule and in line with the large-company dp-closed aggregate markup in the MSI data (1.294).

U.5 Deadpooling

U.5.1 Block Closure Decision

A block is *deadpooled* when an insurer closes it to new enrollment *and* the same parent opens a fresh block in the same market, matching the empirical definition of Section 2.3; closure alone is an ordinary exit and is not deadpooling. We take the closure decision as exogenous, governed by a hazard rate estimated from the market data. Treating it as exogenous to the individual block is supported rather than assumed: closures are coordinated, subsidiary-wide events whose timing is a corporate decision rather than a response to any one block's pool (Appendix G). The annual probability that a parent company initiates a new deadpool in a given year is calibrated to match the observed frequency of block closures in the MSI microdata. Specifically, the deadpooling hazard is modeled as a scaled version of estimates from our calculations from the Mark Farrah data:

$$\Pr(\text{new deadpool in year } t) = h_{\text{MFA}} \times s_h, \tag{30}$$

where h_{MFA} is the estimated baseline (block-age-specific) hazard and $s_h = 1.20$ is a scaling factor. Each open block of a deadpooling parent draws independently against the age-specific hazard; at most one block is closed per state–plan-letter market each year, and if several blocks draw a closure the largest (most-enrolled) is the one closed, reflecting that insurers prefer to maximize the trapped pool.

U.5.2 Closed-Block Premium Dynamics and Lock-in Mechanism

When a block closes, it stops accepting new enrollees. The closed block's risk pool deteriorates through two channels: (i) healthy enrollees exit or switch to cheaper open blocks, and (ii) the remaining pool ages and sickens over time. Closed blocks charge the ramped markup described in Appendix U.4. As healthy consumers depart, average claims rise, triggering further premium increases, which induce more

mobile consumers to exit, further deteriorating the pool.

The underwriting step. Because this is the mechanism the whole model turns on, we set it out separately rather than folding it into the switching rule. An enrollee who has decided to move—having shopped, found a cheaper open block, and judged the saving worth taking—must still be accepted by the receiving insurer. Acceptance is drawn as

$$\Pr(\text{accepted} \mid h, a) \;=\; \max\{0,\; \rho_h - \delta \cdot (a - 65)\}, \qquad \rho_H = 0.95, \quad \rho_M = 0.25, \quad \rho_S = 0.05,$$

with $\delta = 0.010$ per year of age above 65. Three features deserve emphasis.

First, the ρ_h are pass rates *at age 65*, not flat rates. Because the age penalty is subtracted rather than scaled, it bites hardest where the base rate is smallest: a sick enrollee's acceptance probability reaches zero at age 70 and a moderate enrollee's at age 90, while a healthy enrollee's is still positive well beyond the top of the age range. Most enrollees in a closed block are therefore facing acceptance probabilities materially below the headline figures, and for the sick the barrier is absolute rather than probabilistic.

Second, the gradient across health states is what generates the selection channel: it is the *difference* between ρ_H and ρ_M, not their level, that determines how much a closing block cream-skims. Flattening the gradient while holding the average fixed removes the mechanism without changing how much friction enrollees face on average.

Third, underwriting binds only outside a guaranteed-issue window. The birthday-rule and continuous-GI counterfactuals of Section 9.3 operate precisely by waiving this step, which is why they act on lock-in without touching the closure decision itself.

The pass rates are calibrated rather than estimated, and Appendix E reports the independent MCBS-and-filings exercise against which they should be judged: on that evidence the average enrollee would be declined by 68.5% of the company×state markets available to them.

U.6 Simulation Design

U.6.1 Initialization and Timing

The market is initialized with $N_0 = 40{,}000$ enrollees distributed across all active blocks. To reach a realistic stationary distribution, we discard the first 60 years of the 80-year run, reporting outcomes only over the remaining 20 years. Within each period, premiums carried over from the prior year are in force; then new 65-year-olds enroll; then consumers make switching, exit, and re-entry decisions; claims realize; and insurers update next year's premiums.

U.6.2 Policy Transition Design

Policy counterfactuals are implemented as unanticipated regime changes. The baseline regime runs for the first $T_0 = 20$ years, which also serve as the burn-in and establish the calibrated steady state. At year

$T_0 = 20$, the policy regime switches to the counterfactual, and the simulation runs for an additional $T_1 = 60$ years (through year 79) under the new regime. The first T_0 years are the *pre-switch* baseline; they are not the same as the 60 years discarded before reporting, which is the burn-in referred to in Section U.6.

U.6.3 Outcome Aggregation

We report steady-state values averaged over years 60–79, the last 20 years of the 80-year horizon. Every regime, the baseline included, uses this same window; the policy switch occurs at year $T_0 = 20$, so the window opens twenty years after the switch and measures the regime rather than the transition into it. The transitional dynamics are reported separately over the ten years following the switch. Key outcomes include the enrollment-weighted average premium $\bar{P}$, loss ratio $\text{LR} = \bar{c}/\bar{P}$, exit and re-entry rates, share out of market, and three nested deadpooling-share measures: the share of enrollees at a deadpooling company (the calibration target, ϕ^{dp}), the share in a block lineage that ever deadpools, and the share currently sitting in a closed deadpooled block. The deadpool premium excess ΔP^{dp} compares premiums in currently-closed deadpooled blocks to the rest of the market.

U.7 Model Parameters

Table A17 reports all structural parameters of the simulation model, their calibrated or externally assigned values, and their sources.

Table A17. Model Parameters: Most Are Externally Calibrated, Three Fit by Grid Search

Parameter	Symbol	Value	Source / Notes
Panel A: Health and Demographics			
Annual claims, healthy / moderate / sick	$\bar{c}_H, \bar{c}_M, \bar{c}_S$	\$846 / \$1,289 / \$2,337	MCBS PAMTALPR ratios 1 : 1.54 : 2.77, NAIC-anchored (\$2,205 avg)
Claims CV, healthy / moderate / sick	$\text{CV}_H, \text{CV}_M, \text{CV}_S$	2.4 / 2.0 / 1.8	MCBS PAMTALPR; 0–1, 2–3, 4+ chronic conditions
Age claims multiplier, 65 / 75 / 85	$m_c(a)$	1.000 / 1.204 / 1.299	MCBS, normalized at 65
Mortality scale, healthy	μ_0^H	0.015	Relative scale; see age profile below
Mortality scale, moderate	μ_0^M	0.030	SAH RR $\approx 2\times$; Lee et al. (2003)
Mortality scale, sick	μ_0^S	0.080	Assumed; $\approx 5\times$ healthy
Mortality age multipliers	$m_\mu(a)$	see text	Solved to reproduce the SSA life table; $m_\mu(65) = 0.29$, $m_\mu(75) = 0.88$, $m_\mu(85) = 1.45$
$H \to M$ baseline rate	p_{HM}^0	0.06	MCBS health transition matrix
$M \to S$ baseline rate	p_{MS}^0	0.09	MCBS health transition matrix
Age health gradient	δ	0.003/yr	Above age 65
Panel B: Willingness to Pay			

continued on next page

Table A17, continued from previous page

Parameter	Symbol	Value	Source / Notes
WTP horizon	T	20 years	Expected coverage duration from age 65
Risk aversion (CARA)	ρ	1×10^{-4}	Certainty-equivalent WTP loading
WTP center, healthy	$\bar{v}_H$	\$1,821	20-yr Markov forward sim, $h_0 = H$ (at ρ=10^{-4})
WTP center, moderate	$\bar{v}_M$	\$2,716	20-yr Markov forward sim, $h_0 = M$
WTP center, sick	$\bar{v}_S$	\$3,580	20-yr Markov forward sim, $h_0 = S$
WTP coefficient of var.	σ_v	0.40	Calibrated to exit/entry moments
Panel C: Price Sensitivity			
λ distribution mean	μ_λ	0.20	Calibrated to exit-rate moment
λ distribution std	σ_λ	0.20	Calibrated
Panel D: Consumer Behavior			
Exit responsiveness	γ^{exit}	1.80	Calibrated to 5.3% exit rate (risk-averse WTP)
Re-entry responsiveness	γ^{re}	0.50	Calibrated to 1.6% re-entry rate
Shopping probability scale		0.20	Calibrated; applied to λ_i
Savvy attention boost		20.0	Multiplies λ_i in savvy counterfactuals (shop prob capped at 1)
Underwriting pass, healthy	ρ_H	0.95	Industry underwriting tables
Underwriting pass, moderate	ρ_M	0.25	KFF denial rates back-calculated; 18% overall denial
Underwriting pass, sick	ρ_S	0.05	Industry underwriting tables
UW age penalty		0.01/yr	Above age 65; industry tables
Base enrollment, healthy		35%	Calibrated to dp_share moment
Base enrollment, sick		55%	Calibrated to dp_share moment
Panel E: Insurer Pricing and Markup			
Non-DP markup	m^{nd}	1.24	Calibrated (grid search); near MSI non-dp markup 1.239
DP-open markup	$m^{\text{dp-open}}$	1.24	Same as non-dp markup
DP-closed markup	$m^{\text{dp-closed}}$	1.28–1.34	Ramps m^{nd}+0.02 to +0.08 over yrs since closure (calibrated multiplier); near MSI 1.294
Panel F: Deadpooling Hazard			
P(parent has DP block)	p_{dp}	0.14	Calibrated; MFA estimate of the same quantity is 0.293
Hazard scale factor	s_h	1.20	Fixed at max-trapping (dp_share_closed held out)

Notes: The table's structure is the point: the health, mortality, claims, and willingness-to-pay primitives (Panels A–B) are set externally from the MCBS, CDC life tables, and UAS rather than fit to market outcomes, so only four parameters (the non-deadpooled markup, the deadpool markup ramp, the hazard scale, and the deadpooling-parent share) are calibrated internally, and the last two are pinned rather than fit. The successor entry price is not listed because it is not identified by any moment; Section 7.5 shows the data contradict the value the model assumes.

U.8 Are the Stylized Dimensions Adequate?

The model abstracts the market to $F = 37$ parents, $S = 5$ states, and $L = 3$ plan tiers, for up to 555 blocks. The tier count is set to three because Plans F, G, and N cover the great majority of lives, but the three modeled plans are representative tiers calibrated to aggregate market moments rather than models of those particular letters: nothing in the calibration is letter-specific, and the model is not asked to reproduce any letter's benefit design. We justify each choice against the market it stylizes and show that the calibration is insensitive to the two counts that are genuinely free.

Companies, states, and blocks. The real national market contains 239 parent groups, but it is highly concentrated: in 2025 the largest parent holds 34% of covered lives, the top five hold 62%, and the top eight hold 71%. What matters for the deadpooling mechanism is not the long tail of tiny carriers but how many meaningful competitors a beneficiary faces within their own state-and-letter market, and there the median is 11 parents (interquartile range 5 to 30). The model uses 37 parents, above that median but inside the interquartile range. The five states are independent replicas of the no-switching regime the baseline calibrates to (there is no cross-state switching in the model), so the state count governs Monte-Carlo breadth rather than realism.

We report the parent count as a *fit requirement* rather than as a description of the market, because that is what it is. The share of parents that deadpool enters the model only as $\text{round}(N \times \text{share})$, so with a single deadpooling parent the reachable values are multiples of $1/N$, and N is effectively the resolution at which the trapped share can be matched. Reproducing the observed share of lives in a closed deadpooled block requires one deadpooler in roughly thirty-seven. The direction of that requirement is worth noticing: the model needs deadpooling to be done by a *small* carrier, whereas the empirical pattern is the opposite—closures cluster in large national carriers, and closures within a subsidiary are coordinated across letters and states (Appendix G). The model matches the aggregate exposure with one small firm where the market generates it with a few large ones. Nothing in the policy counterfactuals turns on which firms deadpool, since the regimes act on the practice rather than on any firm's identity, but the discrepancy is a limitation of the market structure and not a finding about it.

Robustness to the counts. Average block size, not number of blocks, is what the deadpooling decision's economics turn on—though the reason needs stating carefully, because a *rate* of return is scale-free and would be unchanged by block size. What size changes is the number of dollars a given markup collects: the excess margin on a trapped pool is a percentage, but the parent weighs it against the largely fixed cost of standing up a successor subsidiary, and only the dollar amount scales with the pool. Holding size fixed is therefore the right invariance to impose. We vary the two free counts while

holding average block size fixed (scaling the simulated population with the block count) and re-run the baseline at the calibrated parameters. Table A18 reports the result: taking the number of parents from 16 to 60, and the number of states from 3 to 10, moves the average premium by less than half a percent, the loss ratio and exit rate essentially not at all, and average insurer profit by under one percent. Two caveats attach to that sweep. It was run before the recalibration described in Appendix D (before mortality was re-anchored to the SSA life table, the mobility targets were corrected from stocks to annual flows, and the level of claims by health state was re-derived) so it establishes that the aggregate moments were insensitive to the counts in the earlier parameterisation rather than in the present one. The swept range brackets the 37 parents the calibration selects rather than stopping short of it, so the operative count is inside the range and not an extrapolation from it. The two deadpool-specific micro-moments (the closed-deadpool share and the markup wedge) are noisier because only a handful of closed deadpooled blocks exist in any single run, but they show no systematic trend in either count. The stylized dimensions are adequate: the calibrated market's behavior is a property of block-level economics, not of how many blocks we simulate.

Table A18. The Calibration Is Insensitive to the Number of Companies and States

Varying	Avg. premium	Avg. claims	Loss ratio	Exit rate	Avg. profit
Companies ($S = 5$)					
$F = 16$	\$2,765	\$2,240	0.810	0.0057	\$577
$F = 24$	\$2,762	\$2,237	0.810	0.0057	\$570
$F = 37$	\$2,778	\$2,251	0.810	0.0058	\$567
$F = 48$	\$2,770	\$2,244	0.810	0.0057	\$561
$F = 60$	\$2,764	\$2,239	0.810	0.0058	\$571
States ($F = 37$)					
$S = 3$	\$2,780	\$2,251	0.810	0.0058	\$567
$S = 8$	\$2,770	\$2,244	0.810	0.0058	\$565
$S = 10$	\$2,775	\$2,247	0.810	0.0057	\$565

Notes: Baseline simulation at the calibrated parameters, varying the number of parent companies F (top block, states fixed at $S = 5$) and the number of states S (middle block, companies fixed at $F = 37$), each with $L = 3$ letters. Average block size is held fixed by scaling the simulated population with the block count $F \times S \times L$, so a change in a count is not confounded with a change in block granularity. Each row averages two seeds. The calibration-target row has been dropped: the sweep and the current targets are not stated on the same basis, and the table is a sensitivity across counts rather than a comparison against targets. Aggregate moments and profit are stable to within half a percent across the range; the closed-deadpool share and markup wedge (omitted here) are noisier from small closed-block counts but show no trend in either count.
